ABSTRACT

STUDY OF *PSEUDOMONAS SYRINGAE* EFFECTOR PROTEIN HOPM1 AND ITS HOST TARGET ATMIN7 IMPLICATED IN VESICLE TRAFFICKING IN *ARABIDOPSIS THALIANA*

By

Young Nam Lee

In the pathogenic interaction between *Arabidopsis thaliana* and *Pseudomonas syringae* pv. *tomato* DC3000 (*Pst* DC3000), it has been suggested that one function of type III secretion system (TTSS) effector proteins of *Pst* DC3000 is to interfere with the defense-associated cellular trafficking pathway(s) in *Arabidopsis*. This study focuses on characterization of HopM1, a TTSS effector of *Pst* DC3000, and its host target AtMIN7, a putative adenosine-diphosphate ribosylation factor-guanine nucleotide-exchanging factor (ARF-GEF) implicated in intracellular vesicle trafficking in *Arabidopsis*.

The localization of full-length and truncated HopM1 was studied using confocal microscopy. In tobacco cells, full-length HopM1 fusion proteins were found in small, punctate structures, which were co-localized with a trans-Golgi network (TGN) marker VHA-a1 and an early endosome marker ARA6. The fusion protein of the N-terminus of HopM1 (HopM1$_{1-300}$) was found in punctate structures co-localizing with VHA-a1. Approximately 5 hours after their expression, full-length HopM1 fusion proteins were found in punctate structures, whereas truncated HopM1 fusion proteins (HopM1$_{1-300}$ and HopM1$_{301-712}$) were dispersed in the cells. Full-length HopM1 fusions induced death of tobacco leaf tissue by 48 hours after their induction. Some of the HopM1 fusion proteins transformed into *Arabidopsis* (Col-0 and *atmin7* backgrounds) showed similar localization patterns as in tobacco. It is suggested that HopM1 is localized in the

endosomes in the host cell and that HopM1$_{1\text{-}300}$ contains an organelle-targeting signal.

Whether other *Arabidopsis* ARF-GEFs besides AtMIN7 are involved in host defense is not known. The roles of three ARF-GEFs (*AtBIG2, AtBIG3* and *AtBIG4)* in defense were studied by examination of bacterial multiplication in corresponding T-DNA insertional mutants. None of the examined mutants showed a clear defect in defense against *Pst* DC3000, the ΔCEL mutant (lacking HopM1), or the *hrcC* ⁻mutant (defective in the TTSS). The HopM1$_{1\text{-}300}$ was previously shown to interact with the C-terminus of AtMIN7. The C-termini of four ARF-GEFs (AtBIG1, AtBIG3, GNL1 and GNL2) were examined by yeast two-hybrid assay to determine whether they also interacted with HopM1$_{1\text{-}300}$. The C-terminus of GNL2 did not interact with HopM1$_{1\text{-}300}$. The interactions between HopM1$_{1\text{-}300}$ and the C-termini of AtBIG1, AtBIG3 and GNL1 were not determined because of the failure to express these proteins in yeast.

To determine whether AtMIN7 regulates the secretion of defense-related proteins, three *Arabidopsis* proteins (PR1, a putative lipid-transfer protein encoded by At2g10940, and FLA9, a putative arabinogalactan protein encoded by At1g03870) were fused with GFP, and expressed in *Arabidopsis* (Col-0 and *atmin7* background) followed by confocal microscopic examination. PR1-GFP was localized in the intercellular space both in Col-0 and *atmin7* backgrounds. At2g10940-GFP was localized in the intercellular space in Col-0 background, but in *atmin7* background, unidentified intracellular structures appeared. FLA9-GFP fusion was not expressed in *Arabidopsis*. These results suggest that the localization of At2g10940-GFP may be dependent on the AtMIN7-mediated vesicle trafficking pathway(s) whereas the localization of PR1-GFP is not.

CHAPTER 1

Literature Review

.

General aspects of plant-pathogen interactions

During evolution, plants have been exposed to a variety of micro-organisms and developed various types of interactions with them. Among these interactions, the interactions between plants and pathogenic microorganisms have been extensively studied in plant science, in order to advance our understanding of these processes and how they have been evolved. Moreover, the study of plant-pathogen interactions is important for agriculture, considering that the crop loss caused by plant disease is one of the major limiting factors in food production (reviewed by Savary et al., 2006).

The aspects of the interactions between plants and pathogens are diverse depending on types of plants and pathogens. However, an emerging theme of these interactions is that plants and their pathogens are in a continuous cycle of attack, defense, and counterattack. In this ongoing "battle", the pathogens have continuously affected the physiological state of the plants for obtaining nutrition for their survival and proliferation. In many cases, these effects compromise or severely interfere with the normal physiology, growth and proliferation of plants. Plants have evolved defense mechanisms in order to cope with these pathogen attacks, as summarized in different reviews (Katagiri et al., 2002; Chisholm et al., 2006; Speth et al., 2007; Boller and He, 2009). This evolutionary arms race enabled both pathogens and plants to develop multiple strategies for attack and defense. As a result, this arms race has significantly affected the evolution of plants and pathogens at the genetic and molecular level (Ma et al., 2006; Stavrinides et al., 2008).

The *Arabidopsis thaliana-Pst* DC3000 model

In many cases the interactions between plants and pathogens are specific. Some of these interactions have been studied as model systems, in which a specific plant species and a specific pathogen are connected as an interaction pair. In this thesis, I focus on one plant-pathogen interaction model, in which *Arabidopsis thaliana* is the host plant and *Pseudomonas syringae* pv. *tomato* DC3000 (*Pst* DC3000) is the pathogen. This model was introduced in 1990s with several other *Arabidopsis thaliana-Pseudomonas syringae* interaction models, and has been widely used in plant-pathogen interaction studies since then (Davis et al., 1991; Dong et al., 1991; Whalen et al., 1991; Katagiri et al., 2002). Both *Arabidopsis* and *Pst* DC3000 have advantages for studying the molecular basis of plant-pathogen interactions, because both of them have well-developed resources of molecular genetic and genomic manipulations, including their full genome sequences (for *Arabidopsis* genome, refer to Rhee et al. (2003) and www.arabidopsis.org; for *Pst* DC3000 genome, refer to Buell et al. (2003) and http://pseudomonas-syringae.org).

Pseudomonas syringae *pv.* tomato *DC3000 as a bacterial phytopathogen*

P.syringae is a gram-negative bacterium. It is included in the *Pseudomonas* genus, which has approximately 50 pathogenic species with different host specificities (Deng et al., 1998; Anzai et al., 2000). As a plant pathogen *P.syringae* has more than 50 pathovars (Gardan et al., 1999) which differ largely in host range among different plants (Gardan et al., 1999). Different races and strains are assigned to these pathovars, based on their ability to infect different plant cultivars (Alfano and Collmer, 1997; http://pseudomonas-syringae.org). Pathovars of *P.syringae* infect various crops such as tomato, soybean, rice, tobacco and wheat (Gardan et al., 1999).

Pst DC3000 is a strain included in the pathovar *P.syringae* pv. *tomato*, which is the cause of speck disease in tomato (Cuppels, 1986). Speck disease on tomato is one of the representative examples of disease caused by *P.syringae*, with characteristic symptoms such as necrotic lesions on the tomato leaves and dark spots on the fruit (Cuppels et al., 1990; http://pseudomonas-syringae.org). *Pst* DC3000 is assigned to race 0, on the basis of its avirulence on tomato cultivars carrying Pto resistance (Ronald et al., 1992). *Pst* DC3000 is also a pathogen of *A. thaliana* (Whalen et al., 1991; Katagiri et al. 2002).

Pst DC3000 is considered as a hemibiotrophic pathogen: it typically enters plant leaves through openings such as stomata or through wounds and aggressively multiplies (to the level of 10^8 cells/cm^2 of leaf) in the intercellular space (also known as apoplast), followed by formation of necrotic lesions (Whalen et al., 1991; Hirano and Upper, 2000; Katagiri et al., 2002; Nomura et al., 2005; Melotto et al., 2008). Upon infection by *Pst* DC3000, *A. thaliana* displays disease with visible symptoms, such as leaf yellowing (chlorosis) and the water-soaking phenomenon, followed by eventual tissue necrosis (Whalen et al., 1991; Katagiri et al., 2002).

The pathogenicity and virulence of *Pst* DC3000 depend on at least two pathogenicity factors, the type III secretion system (TTSS) with its effector proteins and the phytotoxin coronatine (Katagiri et al., 2002). *Pst* DC3000 injects 30-40 bacterial proteins collectively called "TTSS effectors" into the plant cells through its TTSS (Alfano and Collmer, 2004). The TTSS of *Pst* DC3000 is encoded by a cluster of hypersensitive response and pathogenicity (*hrp*) genes; *hrp*⁻ mutants of *Pst* DC3000 are impaired in regulation or secretion of type III effectors, and lose the ability to multiply

and cause disease in compatible hosts (Yuan and He, 1996; Roine et al., 1997). The

TTSS (and its effector proteins) and *hrp* genes are not specific to *Pseudomonas*, but

found in other plant pathogens such as *Xanthomonas*, *Ralstonia*, and *Erwinia spp.*

(Alfano and Collmer, 1997; Alfano and Collmer, 2004) and in several animal pathogens

like *Yersinia*, *Salmonella*, and *Shigella spp.* (He et al., 2004).

The TTSS and its effectors are essential for the pathogenicity and virulence of *Pst*

DC3000 and other pathogens (Yuan and He, 1996; Deng et al., 1998; Collmer et al.,

2002). Accumulated research results indicate that TTSS effectors contribute to

pathogenicity and virulence by manipulating the physiological states of host plants

(Nobuta and Meyers, 2005; Cunnac et al., 2009). These manipulations will be further

discussed in later parts of this chapter.

On the other hand, coronatine is a phytotoxin made by several pathovars of

P.syringae including *Pst* DC3000 (Bender et al., 1999). It is composed of two moieties,

coronafacic acid and coronamic acid. The structure of coronatine shares a high similarity

to that of jasmonoyl isoleucine (JA-Ile), and it has been thought that coronatine is a

functional mimic of JA-Ile in plant-pathogen interactions (Katagiri et al., 2002; Melotto

et al., 2008). The role of coronatine in pathogenicity and virulence of *Pst* DC3000 has

been studied in *Arabidopsis* and tomato, and it is generally accepted that coronatine

contributes to symptom development, activation of jasmonate (JA)-related responses and

suppression of the expression of defense-related genes in plants (Mittal and Davis, 1995;

Zhao et al., 2003; Thilmony et al., 2006). The JA-mediated defense pathways and the

salicylic acid (SA)-mediated defense pathways are often antagonistic (Kunkel and Brooks,

2002; Heil and Bostock, 2002), and the suppression of SA-mediated defenses in plants by

coronatine was shown in multiple studies (Zhao et al., 2003; Uppalapati et al., 2007). More recently a role of coronatine in the regulation of stomatal opening was shown (Melotto et al., 2006; Melotto et al., 2008).

Arabidopsis thaliana *as a model plant in plant-pathogen interactions*

Arabidopsis thaliana has advantages in laboratory research due to its small plant size, short generation time (around 8 weeks), high seed production, natural self-pollination, small genome size and well-established genomic resource (Meyerowitz, 1987; Ausubel et al., 1995; Nobuta and Meyers, 2005). *Arabidopsis* has been used as a model plant for studying the interactions with several pathogenic *P.syringae* strains including *Pst* DC3000 and showed clear resistance or susceptibility to different strains of *P.syringae*, depending on the genotypes of those strains (Davis et al., 1991; Dong et al., 1991; Whalen et al., 1991; Ausubel et al., 1995). As mentioned above, *Arabidopsis* exhibits susceptibility to *Pst* DC3000, showing symptom development including water-soaking, chlorosis, and tissue necrosis, followed by death of whole plant (Katagiri et al., 2002).

A four-part model for the interaction between *Arabidopsis* and *Pst* DC3000

The *Arabidopsis-Pst* DC3000 interaction can be explained by a recently suggested "four-part model" (Bent and Mackey, 2007). This model shows the roles of TTSS effector proteins of *Pst* DC3000 in inducing plant resistance and susceptibility (Chisholm et al., 2006; Jones and Dangl, 2006; Bent and Mackey, 2007) and includes two major

concepts of two major plant defenses, PAMP-triggered immunity (PTI) and effector-triggered immunity (ETI). This model also reflects the hypothetical evolutionary steps of the interaction between *Arabidopsis* and *Pst* DC3000.

1st step: the activation of PAMP-triggered immunity (PTI)

In the first part of four-part model, generic, conserved components of micro-organismic pathogens called pathogen-associated molecular patterns (PAMPs), or more recently called microbe-associated molecular patterns (MAMPs: Ausubel, 2005), are perceived by plants. This recognition of PAMPs/MAMPs by plants activates a basal layer of defense responses, which are believed to be sufficient for preventing infections by a wide range of microbes (Alfano and Collmer, 2004; Nomura et al., 2005; Bent and Mackey, 2007). In recent reviews this layer of defense responses are referred to as PAMP-triggered immunity (PTI) (Chisholm et al., 2006; Jones and Dangl, 2006; Bent and Mackey, 2007). In earlier studies PTI was not an independent concept, but it was incorporated in "nonhost" resistance, which allows a given plant species to confer broad-spectrum resistance against most microorganisms (Heath, 2000; Nürnberger and Brunner, 2002; Mysore and Ryu, 2004). In this context PAMPs/MAMPs were studied as "general elicitors" activating defense responses in the species level (Boller, 1995; Nürnberger et al., 2004). However, the PTI is now accepted as the first line of plant defense against different microorganisms.

Well-known PTI-associated defense responses include formation of papillae (localized apposition of callose and other materials) in the plant cell wall, induction of defense genes, accumulation of reactive oxygen species (ROS) and plant secondary

7

metabolites (Alfano and Collmer, 2004; Nomura et al., 2005). Modification of the plant cell wall is likely an important part of plant immunity (Hauck et al., 2003; DebRoy et al., 2004; Keshavarzi et al., 2004).

Various PAMPs/MAMPs have been reported from different pathogens. They include bacterial flagellin, bacterial lipopolysaccharide (LPS), fungal cell wall components like chitin, heptaglucosides of oomycetes, and fungal ergosterol (Nürnberger et al., 2004; Bent and Mackey, 2007). Among these PAMPs/MAMPs, bacterial flagellin (especially the 22-amino-acid conserved epitope in the N-terminus of flagellin (flg22)) has been well studied (Felix et al., 1999; Gomez-Gomez et al., 1999). The flg22 peptide is sufficient to induce PTI (Gomez-Gomez et al., 1999). Recognition of flg22 contributes to enhanced resistance against non-pathogenic bacteria (Hann and Rathjen, 2007). Flg22 is recognized by and binds to *Arabidopsis* FLS2, which is a transmembrane receptor protein with extracellular leucine-rich repeats (LRR) and intracellular protein kinase (Gomez-Gomez et al., 1999; Gomez-Gomez and Boller, 2000; Zipfel et al., 2004; Chinchilla et al., 2006). The recognition of flg22 by FLS2 enhances plant resistance against *Pst* DC3000, presumably through activation of downstream signal transduction pathways, including expression of defense-related genes (Asai et al., 2002; Navarro et al., 2004; Zipfel et al., 2004; Livaja et al., 2008).

Besides flagellin (or its flg22), the elongation factor Tu (EF-Tu) of bacteria was also reported as a PAMP/MAMP (Kunze et al., 2004). EF-Tu induces defense responses in plants including *Arabidopsis,* such as ethylene biosynthesis and oxidative burst (Kunze et al., 2004). Later, another *Arabidopsis* transmembrane LRR-receptor-like kinase, EFR, was reported as the binding receptor of EF-Tu (Zipfel et al., 2006). EFR and FLS2

induce a common set of defense-related responses, including oxidative burst and MAP kinase activation, after recognizing EF-Tu and flg22, respectively (Zipfel et al., 2006). LPS, another example of bacterial PAMPs/MAMPs, extracted from *Xanthomonas campestris* pv. *vesicatoria* induced papilla formation and delay of symptom development in pepper (Keshavarzi et al., 2004).

Although not common, there are a few cases that PAMPs/MAMPs induce localized cell death in nonhost plants. For example, the flagellin monomer or flg22 from *Pst* DC3000 induces cell death in *Nicotiana benthamiana*, which is a nonhost plant to *Pst* DC3000 (Taguchi et al., 2003; Hann and Rathjen, 2007). This cell death is dependent on an orthologue of *Arabidopsis* FLS2 in *N.benthamiana, NbFls2* (Hann and Rathjen, 2007). Also, certain LPS activates the generation of ROS and activations of defense genes associated with local cell death (Desaki et al., 2006).

2nd step: the suppression of PTI by TTSS effector proteins

In the 2nd step of the "four-part model", successful pathogens including *Pst* DC3000 release pathogenic proteins, which target host plants and suppress PTI. TTSS effectors of *Pst* DC3000 is among the most extensively studied examples of PTI suppression by bacterial proteins.

As shown in previous reports, wild type bacterial pathogens with intact TTSS (Kesharvarzi et al., 2004) or even specific TTSS effectors such as AvrPto (Hauck et al., 2003; He et al., 2006; Hann and Rathjen, 2007) suppress PTI. AvrPto was later shown to also suppress flg22-induced MAP kinase signal transduction pathways and early gene expressions for defense (He et al., 2006). Remarkably, it was recently shown that AvrPto

physically interacts with FLS2 or EFR to block innate immunity of *Arabidopsis* (Xiang et al., 2008). In addition to AvrPto, other TTSS effectors of *Pst* DC3000 like AvrPtoB (de Torres et al., 2006; Hann and Rathjen, 2007), HopM1 (DebRoy et al., 2004), HopU1 (Fu et al., 2007), AvrRpt2 and AvrRpm1 (Kim et al., 2005), or HopAO1 (also known as HopPtoD2 [Underwood et al., 2007; Guo et al., 2009]) suppress PTI.

The local cell death in nonhost plants is also a target of some TTSS effectors. AvrPto and AvrPtoB expressed in *Nicotiana benthamiana* suppresses the localized PAMP-induced cell death (Kang et al., 2004; Hann and Rathjen, 2007). There are cases in which the induction of certain plant genes during PTI is suppressed by TTSS effectors (de Torres et al., 2006; He et al., 2006; Underwood et al., 2007).

The suppression of PTI by the TTSS effectors often contributes to the enhanced multiplication of non-pathogens or mutants of virulent pathogens, as shown in the cases of AvrPto or AvrPtoB (Hauck et al., 2003; He et al., 2006; de Torres et al., 2006; Hann and Rathjen, 2007).

3rd step: the recognition of TTSS effectors by plants and activation of effector-triggered immunity (ETI)

The third part of the four-part model is essentially the classic gene-for-gene interaction model (Flor, 1971), in which TTSS effectors are recognized by plant resistance (R) proteins, followed by the eliciting of defense responses called the hypersensitive response (HR). It is a relatively recent trend that the gene-for-gene interaction is incorporated in the bigger plant-pathogen interaction model emphasizing its evolution as a counterattack to the suppression of plant defenses by TTSS effectors, and

it is called effector-triggered immunity (ETI) (Chisholm et al., 2006; Jones and Dangl, 2006; Bent and Mackey, 2007).

Gene-for-gene resistance was studied in the context of specific plant genotypes (for instance, cultivars) and specific pathogen genotypes (strain or race). According to this model, a plant-pathogen interaction can be compatible (leading to plant disease) or incompatible (leading to plant resistance). The incompatible interaction occurs when the plant expresses a specific plant resistance gene (*R*) and the (avirulent) pathogen expresses a specific avirulence (*avr*) gene (Dangl and Jones, 2001). During the incompatible interaction, downstream signal transduction pathways lead to defense responses, such as the expression of pathogenesis-related (PR) genes (Uknes et al., 1992), the rapid and localized cell death in the infected region (HR) (Heath, 2000), and the activation of systemic acquired resistance (SAR).

Many *avr* and *R* gene pairs have been discovered in various plant-pathogen interactions (Martin et al., 2003; Alfano and Collmer, 2004). In the four-part model, bacterial Avr proteins (TTSS effectors) suppress basal defense, and the R proteins detect this defense-suppressing virulence factors by detecting the effect of a TTSS effector on the designated host protein. The host protein which is affected by the TTSS effector is indispensable to the plant defense (Chisholm et al., 2006; Bent and Mackey, 2007). Initially it was thought that Avr proteins and R proteins were directly interacting and that this interaction activates downstream defense pathways. This is based on several examples of direct interactions between Avr proteins and R proteins, such as the interaction between Pi-ta of rice and AVR-Pita of rice blast fungus (*Magnaporthe grisea*) (Jia et al., 2000) and that between R proteins of flax and AvrL567 variants of rust

(*Melampsora lini*) (Dodds et al., 2006). However, this was not the case for the majority

of Avr-R interactions, and an alternative explanation called "guard hypothesis" was

introduced (Dangl and Jones, 2001). In this hypothesis, Avr proteins interact with and

manipulate plant target proteins which are independent of, but often physically associated

with, R proteins. This indirect recognition of Avr protein by R protein through the third

plant target protein induces downstream defense pathways. The interaction between

AvrPto of *P.syringae* and tomato proteins Pto and Prf is explained by the guard

hypothesis: AvrPto physically interact with Pto (Scofield et al., 1996; Tang et al., 1996),

which may be a virulence target in tomato, and this interaction is recognized by Prf

followed by HR (Salmeron et al., 1996; van der Biezen and Jones, 1998; Dangl and Jones,

2001; Zipfel and Rathjen, 2008). Other TTSS effectors of *P.syringae*, AvrRpm1, AvrB or

AvrRpt2 phosphorylates or eliminates RIN4, which is a regulator of basal defense of

Arabidopsis, and these modifications of RIN4 activate RPM1- or RPS2-mediated defense

responses (Mackey et al., 2002; Axtell and Staskawicz, 2003; Mackey et al., 2003).

Recently another model referred to as "decoy model" was introduced for

explaining the relationship between Avr protein (TTSS effector), its corresponding R

protein and the plant target protein of Avr protein. Compared to the guard hypothesis, in

the decoy model the plant protein targeted by Avr protein (TTSS effector) does not have

functions in virulence, and this target protein works as a decoy to detect pathogen

effector protein (Zipfel and Rathjen, 2008; van der Hoorn and Kamoun, 2008).

4th part: evasion or suppression of ETI by pathogens through TTSS effectors

12

In the final part of the four-part model, ETI activated by the recognition of TTSS

effectors by plant R proteins are evaded or suppressed (Bent and Mackey, 2007). The

suppression of ETI is summarized in several reviews (Abramovitch and Martin, 2004;

Nomura et al., 2005; Grant et al., 2006).

The HR induced by gene-for-gene resistance can be suppressed by TTSS effectors.

Ritter and Dangl (1996) reported that AvrRpt2 suppresses HR and disease resistance

activated by the AvrRpm1-RPM1 interaction in *Arabidopsis*. This suppression of HR by

AvrRpt2 is mediated by the action of AvrRp2 as a cysteine protease, cleaving

Arabidopsis RIN4 which is required for HR activated by the AvrRpm1-RPM1 interaction

(Axtell et al., 2003; Mackey et al., 2003). In addition, in the interaction between

P.syringae pv. *phaseolicola* and soybean, it was shown that the TTSS effectors of

P.syringae pv. *phaseolicola* can suppress HR induced by gene-for-gene resistance on the

cultivar level (Jackson et al., 1999; Tsiamis et al., 2000). On the other hand, Abramovitch

et al. (2003) showed that HR induced by AvrPto-Pto was suppressed by AvrPtoB;

however, this result is based on the transient expression of AvrPto, Pto and AvrPtoB in

the nonhost plant *N. benthamiana,* not in the host plant tomato or *Arabidopsis*.

Systemic acquired resistance (SAR)

Systemic acquired resistance (SAR) is a long-lasting, broad-spectrum resistance

which is systemically induced in plant by pathogen infection (Durrant and Dong, 2004)

and not included in the four-step model. SAR is usually activated during the incompatible

interaction between a pathogen with an *avr* gene and a plant with an *R* gene (with HR).

However, non-HR-inducing bacteria also can activate SAR through their

13

PAMPs/MAMPs, showing the systemic resistance against bacterial infection, accumulation of SA and defense-associated gene transcripts (such as flg22 or LPS: Mishina and Zeier, 2007). During SAR, local and systemic accumulation of salicylic acid (SA) occurs, followed by expression of defense-related genes such as pathogenesis-related (PR) genes and activation of signal transduction cascades (Durrant and Dong, 2004; Vlot et al., 2008).

Salicylic acid (SA) is an essential signal for SAR (Gaffney et al., 1993), and exogenous application of SA (Ryals et al., 1995) or SA analogues such as benzothiadiazole (BTH) or 2,6-dichloroisonicotinic acid (INA) can activate SAR as well (Uknes et al., 1992; Lawton et al., 1996). However, SA itself is not a mobile signal for activating SAR in systemic tissue (Vernooji et al, 1994). Several metabolites such as methyl salicylate (MeSA), jasmonic acid (JA) or azaleic acid were suggested as potential mobile signals in SAR (Park et al., 2007; Truman et al., 2007; Jung et al., 2009). Research results show that SA induces redox reactions to reduce the protein NPR1 (non-expressor of pathogenesis-related 1, also known as non-immunity 1 (NIM1)), which is activated and moves to the nucleus of the plant cell in order to activate transcription of defense-related genes. This activation is regulated by several proteins in plants. Also, there are NPR1-independent signaling pathways affecting SAR activation and regulation (Durrant and Dong, 2004; Grant and Lamb, 2006; Loake and Grant, 2007). SA-mediated defense signaling pathway is also affected by cross-talk with other signaling pathways, including JA/ethylene, abscisic acid (ABA), and nitric oxide (NO)-mediated signaling pathways (Loake and Grant, 2007).

Suppression of defense-associated cellular trafficking pathway in plants by TTSS effectors

Recent literature suggests that plant vesicle trafficking machineries are associated with PTI, ETI and SAR, and are a target of TTSS effector-mediated suppression. The importance of vesicle trafficking system in plant defense was initially suggested from studies of cell wall-associated PTI, the formation of papillae. As briefly mentioned above, the papilla is a microscopic apposition which is formed in the intercellular space of the plant (apoplast) (Smart et al., 1985); it consists of heterogeneous materials such as callose (β-1,3-glucan), phenolics and proteins (reviewed by Schmelzer, 2002). Papilla formation were reported in the interactions between fungal pathogens (such as *Blumeria graminis* or *Erysiphe graminis*) and plants (Zeyen and Bushnell, 1979; Smart et al., 1985; Koga et al., 1990; Mendgen et al., 1995; Collins et al., 2003; Gjetting et al., 2004), as well as those between bacterial pathogens such as *P. syringae* or *Xanthomonas campestris* (Bestwick et al., 1995; Brown et al., 1995) and plants. Papillae also can be induced by treatment of PAMPs/MAMPs such as flg22 (Gomez-Gomez et al., 1999; Zipfel et al., 2004; de Torres et al., 2006).

It has been suggested that the cellular vesicle trafficking pathway is important for papilla deposition. Although callose is synthesized in the plasma membrane (Turner et al., 1998; Jacobs et al., 2003; Nishimura et al., 2003), earlier research results suggested that polarized vesicle trafficking may be involved in the formation of papillae (Bestwick et al., 1995; Mendgen et al., 1995). Later, more evidence showing that components of vesicle trafficking pathways of plants play roles in papilla formation was obtained. In particular, mutation of the *Arabidopsis PEN1* gene which encodes a plasma membrane syntaxin

15

(SYP121), which is a member of soluble *N*-ethylmaleimide-sensitive factor adaptor

protein receptors (SNAREs) involved in vesicle docking to a target membrane (Bassham

et al., 2008), resulted in delayed papilla formation in response to a fungal pathogen

Blumeria graminis f.sp. *hordei* (*Bgh*) (Collins et al., 2003). Also, both PEN1 and its

closest homologue SYP122 accumulated at the papilla formation site upon *Bgh* infection,

indicating that vesicle trafficking plays an important role in papilla formation (Collins et

al., 2003; Assaad et al., 2004).

Another syntaxin from *Nicotiana benthamiana, Nb*SYP132 (an orthologue of

SYP132 in *Arabidopsis*), is required for gene-for-gene resistance activated by the

AvrPto-Pto interaction and for extracellular accumulation of the PR1 protein. *Nb*SYP132

contributes to basal defense against the *hrpA⁻* mutant of *Pst* DC3000 and SA-associated

defense (Kalde et al., 2007). Also, an ER-chaperone BiP2 was required for SA-associated

defense responses and PR1 accumulation in Arabidopsis (Wang et al, 2005). In addition,

the importance of cellular trafficking in plant defense is suggested in several studies of

gene expression profiling: microarray data of Wang et al. (2005) showed that protein

secretion pathway-associated genes were included in the primary targets of *Arabidopsis*

NPR1, which is a key regulator of SAR.

Hauck et al. (2003) showed that around 40% of the *Arabidopsis* genes which are

suppressed by a TTSS-dependent manner encoded putative secretion-related proteins.

Similar results were obtained later in a whole-genome microarray study (Thilmony et al.,

2006). Supporting evidence for the hypothesis that TTSS effectors suppress defense-

associated cellular trafficking pathway(s) comes from the following studies: one of the

putative host cellular targets of AvrPto is *Arabidopsis* RabE1d, which is involved in

vesicle targeting (Speth et al., 2009). A TTSS effector of *Xanthomonas campestris* pv.

vesicatoria (XopJ) suppresses cell wall-associated PTI by interfering with plant protein

secretion (Bartetzko et al., 2009). Finally, research on the *Pst* DC3000 effector HopM1

provide more detailed information, as summarized below, about the action of a TTSS

effector on the defense-associated trafficking mechanisms in host plants (Badel et al.,

2003; DebRoy et al., 2004; Badel et al., 2006; Nomura et al., 2006).

HopM1 and AtMIN7: a TTSS effector involved in the suppression of defense-

associated cellular trafficking pathway(s) and its target in Arabidopsis

HopM1 is one of the TTSS effectors whose contribution to the virulence of *Pst*

DC3000 was experimentally confirmed (Badel et al., 2003; DebRoy et al., 2004). The

virulence-associated functions of HopM1 were mainly studied in cell wall-associated

PTI: transgenic expression of HopM1 in *Arabidopsis* plants caused suppression of papilla

formation, restored multiplication of the *Pst* DC3000 ΔCEL mutant, in which *hopM1* and

several adjacent TTSS effector genes are deleted (Alfano et al., 2000), and eventually

caused tissue death (Nomura et al., 2006). Nomura et al. (2006) found that HopM1

interacts and destroys several *Arabidopsis* proteins (AtMINs), including AtMIN7.

AtMIN7 is a member of the *Arabidopsis* adenosine-diphosphate ribosylation factor-

guanine nucleotide-exchanging factor (ARF-GEF) family, whose members have roles in

vesicle formation for intracellular trafficking (Memon, 2004; Gillingham and Munro,

2007; Anders and Jürgens, 2008; Bassham et al., 2008). T-DNA insertional mutants of

AtMIN7 show enhanced multiplication of the ΔCEL mutant of *Pst* DC3000 (Nomura et

al., 2006). Also, callose deposition in papillae of *atmin7* by the ΔCEL mutant is reduced

17

compared with that in wild-type Arabidopsis plants (Nomura et al., 2006). Therefore, AtMIN7 functions in the defense-associated vesicle trafficking pathway(s), and HopM1 interferes with the action of AtMIN7 by degrading it.

Summary of thesis research subjects

One of the major questions in the study of plant-pathogen interactions is how a virulent pathogen suppresses the plant defense mechanisms. Various mechanisms of suppression of plant defenses by pathogens have begun to be determined. In the interaction between *Pst* DC3000 and *Arabidopsis thaliana*, it has been suggested that one function of TTSS effector proteins of *Pst* DC3000 is to interfere with the defense-associated cellular trafficking pathway(s) in *Arabidopsis*. The strongest evidence for this comes from the discovery of the action of HopM1 on AtMIN7 in *Arabidopsis* (Nomura et al., 2006). The activity of HopM1 on a regulator of vesicle trafficking is intriguing and raises a number of questions for further study. My thesis research focuses on answering some of these questions.

In chapter 2, I describe the results of my study to determine the subcellular localization of HopM1 in plant cells. In a membrane fractionation experiment, HopM1 was not present in the plasma membrane, but was detected in an unidentified endomembrane compartment of *Arabidopsis* cells (Nomura et al., 2006). To more precisely determine the localization of HopM1 in plant cells, I constructed fusions of HopM1 with fluorescence proteins, and examined the localization of these fusion proteins by confocal microscopy.

As mentioned above, there are seven other ARF GEF genes in Arabidopsis, besides AtMIN7 (Cox et al., 2004; Anders and Jürgens, 2008). In chapter 3, I describe my study to determine whether any of these other *ARF-GEF* genes has a role in defense. Nomura et al (2006) studied this possibility with a few *ARF-GEF* genes, but not all *ARF-GEF* genes were studied. Therefore, I focused on the unstudied *ARF-GEF* genes using two approaches: one was yeast two-hybrid assay between ARF-GEFs and HopM1 in order to determine whether HopM1 interact with those ARF-GEFs in addition to AtMIN7. The other was the investigation of multiplication of the ΔCEL mutant in T-DNA insertional mutants of these ARF-GEF genes to determine if mutants of other *ARF-GEF* genes, like *atmin7*, also showed enhanced multiplication of the ΔCEL mutant.

In chapter 4, I describe a study of several defense-associated *Arabidopsis* extracellular proteins. By tagging them with fluorescence proteins and confocal microscopic examination, I monitored the localization of those fluorescence protein fusions in wild type and *atmin7* background to determine whether the secretion of these selected *Arabidopsis* extracellular proteins is affected in the *atmin7* background.

ACKNOWLEDMENTS

ABSTRACT

HopM1, a bacterial effector protein secredted through the type III secretion system (TTSS), is important for the virulence of *Pseudomonas syringae pv. tomato* (*Pst*) DC3000. HopM1 interacts with and mediates degradation of several *Arabidopsis* proteins (AtMINs), including AtMIN7. AtMIN7 is a putative ARF-GEF protein, which has a role in vesicle formation and budding during intracellular trafficking. To further understand the action of HopM1 in host cells, I studied the subcellular localization of HopM1 in tobacco and *Arabidopsis*. Full-length HopM1 and its truncated versions (HopM1$_{1-300}$ and HopM1$_{301-712}$) were fused with GFP or YFP, and they were transiently expressed in tobacco followed by examination by confocal microscopy. After 8 hours of DEX-induction, full-length HopM1 fusion proteins caused tissue death in tobacco leaves, in contrast to truncated HopM1 fusion proteins which did not induce tissue death.

Approximately between 2.5 hours and 4 hours after DEX-induction, full-length HopM1 and HopM1$_{1-300}$, which were fused with GFP or YFP, were found in small, punctate structures in tobacco cells. These small structures were co-localized with VHA-a1-RFP, a marker for trans-Golgi network (TGN), and ARA6-CFP, a marker for early endosome. They were not co-localized with ST-RFP (a Golgi marker). After 4 to 6 hours, full-length HopM1 fusion proteins were still detected in punctate structures, but truncated HopM1 fusion proteins were found dispersed in the tobacco cells. These data indicate that HopM1 is localized in certain parts of the endosomal components, suggesting that its virulence function affects vesicle trafficking in host cells. Also, HopM1$_{1-300}$ is sufficient for the localization in the endosomal compartments.

HopM1 fusion constructs were transformed into *Arabidopsis* Col-0 (wild type), and some were also transformed into the *atmin7* plants. Eight hours after DEX-induction, full-length HopM1 fusion constructs were found in small, punctate structures, whereas the fusions of HopM1$_{1-300}$ were dispersed in *Arabidopsis* cells. This localization is consistent with the localization of HopM1 fusion proteins in later time points of microscopic observation in tobacco cells.

INTRODUCTION

Research on TTSS effector proteins of *Pst* DC3000 in *Arabidopsis* led to the
hypothesis that one of their virulence functions is to interfere with the secretion of
defense-associated proteins of host plants. This hypothesis was suggested based on a
cDNA microarray analysis of *Arabidopsis* (Hauck et al., 2003): *Pst* DC3000 suppressed
the expression of certain *Arabidopsis* genes, around 40% of which encoded putative
secreted proteins. This biased suppression of gene expression occurred in a TTSS-
dependent manner (Hauck et al., 2003).

Other reports also showed that intracellular trafficking and protein secretion
pathways have roles in plant defense: several defense-associated proteins are components
of trafficking pathways, such as PEN1 or *Nb*SYP132 (Collins et al., 2003; Assaad et al.
2004; Kalde et al., 2007). Also, protein secretion pathway-associated genes are among
the targets of *Arabidopsis NPR1*, which is a key regulator of systemic acquired resistance
(SAR; Wang et al., 2005). Direct evidence for the suppression of trafficking pathways
and protein secretion by TTSS effectors was provided by Nomura and colleagues
(Nomura et al., 2006), who showed that a *Pst* DC3000 effector, HopM1, mediates 26S-
proteasome-dependent degradation of AtMIN7, which is a member of the adenosine-
diphosphate ribosylation factor-guanine nucleotide-exchanging factor (ARF-GEF) family
of proteins necessary for the initiation of vesicle trafficking (Memon, 2004; Gillingham
and Munro, 2007; Anders and Jürgens, 2008; Bassham et al., 2008).

The *hopM1* ORF is located in the conserved effector locus (CEL) cluster in the
genome of *Pst* DC3000 (Alfano et al., 2000; Buell et al., 2003). Other ORFs present in

the CEL encode additional TTSS effectors, including AvrE, HrpW1, and HopPtoA1

(Alfano et al., 2000). HopM1 is translocated into plant cells with the assistance of its

chaperone ShcM (Alfano et al., 2000; Badel et al., 2003). The *hopM1* ORF (also known

as ORF3: Alfano et al., 2000) consists of 2,139 bases, encoding a protein of 712 amino

acids (predicted molecular weight:75.23 kDa [Buell et al., 2003;

http://www.ncbi.nlm.nih.gov/, NC_004578.1]).

HopM1 is important for *Pst* DC3000 virulence. Reduced multiplication and

symptom development were observed when *Arabidopsis* was inoculated with the ΔCEL

mutant of *Pst* DC3000. This virulence defect of ΔCEL mutant was restored by a plasmid

carrying the *hopM1* gene and its chaperone gene *shcM* whose product is required for the

translocation of HopM1 into plant cell (Badel et al., 2003; DebRoy et al., 2004).

Transgenic expression of HopM1 in *Arabidopsis* plants caused two phenotypes: 1) Low-

level expression restored multiplication of the ΔCEL mutant, and 2) High-level

expression induced host cell death (Nomura et al, 2006). Interestingly, when the N-

terminal 300 amino acids of HopM1 (HopM1$_{1-300}$) were expressed in *Arabidopsis*, it did

not enhance the multiplication of the ΔCEL mutant, suggesting that HopM1$_{1-300}$ is not

functional. Moreover, transgenically expressed HopM1$_{1-300}$ suppressed the multiplication

of the ΔCEL mutant complemented with full-length *hopM1* and its chaperone *shcM*

(Nomura et al., 2006). This dominant negative effect was not found with the C-terminus

of HopM1 (HopM1$_{301-712}$) (Nomura et al., 2006).

Immunoblot analyses by Nomura et al. (2006) showed that HopM1 is found in the

endomembrane fractions of transgenic *Arabidopsis* cells. However, the endomembrane

system includes many different compartments, and the exact subcellular localization of

37

HopM1 remains elusive. In this study, I used the fluorescence tagging approach combined with confocal microscopy to investigate the subcellular localization of HopM1 in tobacco and *Arabidopsis* cells. By determining the cellular localization of HopM1 in the plant cells, I expect to obtain a more complete understanding of the virulence action of HopM1 inside the host cells. I also examined the localization of the N-terminus of HopM1 (HopM1$_{1-300}$), which has a dominant-negative effect, and that of the C-terminus of HopM1 (HopM1$_{301-712}$) to explore a possible relationship between the cellular localization and virulence function of HopM1.

MATERIALS AND METHODS

Construction of HopM1 fusions

Full-length or truncated *hopM1* ORFs were selected for fusion construction. Computer prediction based on the amino acid sequence of HopM1 did not give a clue of subcellular targeting signals (http://www.cbs.dtu.dk/services/TargetP: Emanuelsson et al., 2007; http://psort.ims.u-tokyo.ac.jp: Nakai and Kanehisa, 1991). Therefore, to avoid possible interference with hidden subcellular targeting signals at the N- or C-terminus, both N-terminal and C-terminal GFP/YFP fusion were designed per each fusion construct (Table 2-1, Figure 2-1).

Synthetic green fluorescence protein (sGFP: Chiu et al., 1996) and enhanced yellow fluorescence protein (EYFP: Clontech, Mountain View, CA) were selected for fusion construction. The ORFs of sGFP and EYFP were amplified by PCR using *PfuTurbo*® DNA polymerase and relevant primers (Table 2-2). The PCR products were subcloned into the pBluescript II SK(+) (Stratagene, La Jolla, CA) using T₄ ligase (New England Biolabs, Ipswich, MA), at its *PstI/SpeI* sites and *XhoI/EcoRI* sites, respectively. Mutation-free fusion ORFs were selected for the next cloning steps.

Full-length *hopM1* ORF was amplified by PCR with *PfuTurbo*® DNA polymerase (Stratagene, La Jolla, CA) using the genomic DNA of *Pst* DC3000 and primers covering the whole ORF (Table 2-3). The sequence of the PCR product was compared to the sequence of *hopM1* ORF deposited in the NCBI (http://www.ncbi.nlm.nih. gov/, NC_004578.1). Mutation-free *hopM1* ORF was cloned into a GATEWAY-compatible vector pENTR/D-TOPO (Invitrogen, Carlsbad, CA) and used as a template for further

The N-terminus of *hopM1* indicates a truncated ORF encoding 1-300 amino acids. The C-terminus of *hopM1* indicates a truncated ORF encoding 301-712 amino acids. *Xho*I, *Eco*RI, *Pst*I, and *Spe*I indicate the restriction enzyme sites added for fusion construction. (A) A diagram of the HopM1-GFP fusion. (B) A diagram of the YFP-HopM1 fusion. (C) A diagram of the HopM1-N-GFP fusion. (D) A diagram of the YFP-HopM1-N fusion. (E) A diagram of the HopM1-C-GFP fusion. (F) A diagram of the YFP-HopM1-C fusion.

PCRs to obtain full-length or truncated HopM1 ORFs. Primers for the PCRs are shown in

Table 2-3. Full-length and truncated *hopM1* ORFs were obtained by PCRs with

PfuTurbo® DNA polymerase (Stratagene, La Jolla, CA). The PCR products of full-length

or truncated *HopM1* ORFs were subcloned into the multiple cloning sites next to the 3'

end of the *EYFP* ORF in pBluescript II SK(+) (*XhoI/Eco*RI sites) in order to generate

YFP-hopM1, *YFP-hopM1-N* and *YFP-hopM1-C* fusion ORFs. Alternatively, they were

subcloned into the multiple cloning sites next to the 5' end of the *sGFP* ORF in

pBluescript II SK(+) (*Eco*RI/*Spe*I sites) to construct *hopM1-GFP*, *hopM1-N-GFP* and

hopM1-C-GFP fusion ORFs. All of these fusion ORFs were sequenced and mutation-

free gene fusions were selected. The *hopM1-C-GFP* fusion was excluded from furtherh

experiments due to its mutations introduced during PCR.

Introduction of HopM1 fusion ORFs into *Agrobacterium*

The mutation-free fusion ORFs were subcloned into the *XhoI/Spe*I sites of the

pBD vector (a gift From Dr. Jeff Dangl laboratory, University of North Carolina, Chapel

Hill, NC). This is a binary vector containing a kanamycin-resistance gene for selecting

bacterial transformants, and a BASTA (glufosinate)-resistance gene for selection of

transgenic plants. The expression of the transgene in pBD vector depends on a promoter

inducible by the rat glucocorticoid hormone dexamethasone (DEX, Aoyama and Chua,

1997). The recombinant pBD plasmids were transformed into *E.coli* strains (DH5α, One

Shot® TOP10 competent cell (Invitrogen, Carlsbad, CA), or One Shot® Mach™-T1[R]

(Invitrogen, Carlsbad, CA)), and kanamycin-resistant colonies were obtained on the solid

Luria-Bertani (LB) medium with kanamycin (50 mg/ml). The kanamycin-resistant *E.coli*

Table 2-3. PCR primers for obtaining full-length or truncated *hopM1* ORFs for fusion constructions.

colonies containing the fusion ORFs were used for introducing recombinant plasmids into *Agrobacterium* strain C58C1 by tri-parental mating using the *E.coli* helper strain pRK2013.

Transient assays of the HopM1 fusion ORFs in tobacco plants

Transient assays were performed in the leaves of *Nicotiana benthamiana* or *Nicotiana tabacum* plants. The protocol for *Agrobacterium* preparation for transient assay was adapted from the experimental methods of Goodin et al. (2002). Each *Agrobacterium* carrying desirable *hopM1* fusion plasmids was inoculated in LB liquid medium with antibiotics (rifampicin, tetracycline and kanamycin) and incubated at 28-30°C for 8-9 hours with shaking at 250 rpm, until the OD_{600} of *Agrobacterium* reached 0.8-0.9. These cultures were centrifuged at 3,000 rpm in a Beckman GS-6R tabletop centrifuge at room temperature. The pellet of each culture was resuspended in the induction medium (10 mM $MgCl_2$, 10mM MES [pH 5.6], 150 μM acetosyringone [3',5'-Dimethoxy-4'-hydroxyacetophenone: Sigma-Aldrich, St. Louis, MO]) and the OD_{600} was adjusted to 0.1-0.2. These re-suspended cultures were collected in sterile test tubes, covered with sterile caps, and left at room temperature for 2-3 hours prior to their injection into tobacco leaves. Each culture was hand-infiltrated with 1 ml needless syringe into leaves and inoculated plants were left for 36-48 hours prior to DEX treatment.

Transformation of HopM1 fusions into *Arabidopsis* plants

The HopM1 fusions were transformed into *Arabidopsis* plants (Col-0 or *atmin7* knockout mutant) by floral dipping (Clough and Bent, 1998). T_1 seeds were collected and

germinated in soil. Ten-day-old T_1 plants were sprayed with 0.2 % BASTA solution

(glufosinate-ammonium, trade name Finale, AgroEvo Environemntal Health, Montvale,

NJ) containing 0.025% Silwet L-77. One leaf from each BASTA-survived T_1 plant was

detached and dipped in a DEX solution (30 μM) and observed with confocal microscopy,

in order to examine the expression of the fluorescent fusion proteins.

Plant growth condition

Tobacco plants were raised in the laboratory, at the room temperature, using a

light of 300 microeinstein. *Arabidopsis* plants were grown in soil in growth chambers,

under a 12 hr dark/12 hr light cycle. The light was with 100 microeinstein, and the

temperature was 20°C.

Application of Dexamethasone (DEX)

DEX powder (Sigma-Aldrich, St. Louis, MO) was dissolved in 100% ethanol at

30 mM, and stored at -20°C. This solution was diluted in water to 15-30 μM just before

spraying, dabbing or dipping. For spraying, 0.01 % surfactant Tween-20 (Sigma-Aldrich,

St. Louis, MO) was added, as suggested by Aoyama and Chua (1997). DEX spray was

performed at least 36 hours after *Agrobacterium* infiltration. DEX solution was either

sprayed on the surface of tobacco leaves with Tween-20 or dabbed on the leaf surface

without Tween-20. The time allowed for DEX induction was variable, between 2 hours

and 48 hours, depending on experiments. *Arabidopsis* leaves were detached from the

plants and dipped in 30μM DEX solution, at room temperature for at least 8 hours.

Confocal microscopy

Leaf samples (5 mm x 5 mm) were cut from the *Agrobacterium*-infiltrated areas of tobacco leaves and mounted in water. The confocal microscopy and imaging were performed with a LSM510 META inverted confocal laser scanning microscope (hereafter META: Carl Zeiss MicroImaging, Inc., Thornwood, NY) or FV1000D laser confocal scanning microscope (hereafter FV1000D: Olympus America Inc., Center Valley, PA). The 40x or 60x oil immersion objectives were used.

The GFP fusions were excited at 488 nm from the argon laser of META, and the emission light was filtered with a 505-530 nm band-pass filter for obtaining GFP fluorescence, and with a 615 nm long-pass filter for obtaining autofluorescence from chloroplasts. The YFP fusions were excited at 514 nm from the argon laser of META, or at 515 nm from the multi-argon laser of FV1000D. The emission light of YFP was filtered with a 520-555 nm band-pass filter of META, or with a 535-565 nm band-pass filter of FV1000D. For these experiments the autofluorescence from chloroplasts was not collected. The images obtained from the confocal microscopy with META were examined and processed with Carl Zeiss AIM Version 3.2. Some images were adjusted for brightness or contrast using Adobe Photoshop Element version 5.5 or 7.0.

Dual localization with cellular markers

The following subcellular markers fused with red fluorescence protein (RFP, monomer of dsRED: Campbell et al., 2002) or dsRED2 (Clontech, Mountain View, CA) were selected for dual localization experiments with HopM1-GFP or YFP-HopM1 in

Agrobacterium-mediated transient expression assays: rat sialyl transferase fused to RFP

(ST-RFP [Saint-Jore et al., 2002; a gift from Dr. Federica Brandizzi, MSU, East Lansing,

MI]), dsRED2 fused with the conserved C-terminal, peroxisome-targeting signal type 1

(PTS1) consisting of serine-lysine-leucine (PTS1-dsRED2 [Gould et al.,1989; Reumann,

2004; Fan et al., 2005]), a CFP-fusion of the endosomal compartment marker ARA6

(ARA6-CFP [Ueda et al., 2001]), and a RFP-fusion of the trans-Golgi network marker

VHA-a1 (VHA-a1-GFP [Dettmer et al., 2006]). All of these markers are constitutively

expressed in plants from the CaMV 35S promoter. Procedures for dual localization

experiments were the same as those of transient assays for HopM1 fusions. The

Agrobacterium culture containing each marker gene was mixed with the *Agrobacterium*

culture of the desired HopM1 fusion gene in a 1:1 ratio.

Dual localization with HopM1-GFP and ST-RFP or PTS1-dsRED2 was

performed with META. The condition of confocal microscopy for HopM1-GFP was the

same as described in page 46. ST-RFP or PTS1-dsRED2 were excited at 543 nm Helium-

Neon laser, and emission light from the RFP or dsRED2 was filtered with a 560 nm long-

pass filter or with the 560-615 nm band-pass filter. Dual localization of YFP-HopM1 and

ARA6-CFP was performed with META or FV1000D. The condition of confocal

microscopy for YFP-HopM1 was the same as described in page 46. ARA6-CFP was

excited by 458 nm laser of META or FV1000D, and the emission light was filtered by a

465-510 nm band-pass filter of META or by a 465-510 nm band-pass filter of FV1000D.

Dual localization was performed in a sequential mode to avoid false signal. The

examination and processing procedure for the images acquired from the confocal

microscopy for dual localization are identical to those described in page 46.

Brefeldin A (BFA) treatment

The fungal toxin Brefeldin A (BFA, γ,4-Dihydroxy-2[6-hydroxy-1-heptenyl]-4-cyclopentanecrotonic acid λ-lactone) extracted from *Penicillium brefeldianum* was purchased from Sigma-Aldrich (St. Louis, MO). A stock of 1.8 mM BFA (10mg/ml) was prepared in 100% methanol and stored at -20°C. For BFA treatment of tobacco leaf samples, 360 μM BFA solution was prepared in water, and tobacco leaf samples which had been hand-infiltrated with *Agrobacterium* cultures carrying HopM1-GFP and ST-RFP plasmids were treated with DEX to induce the expression of HopM1 fusions, and then immersed in the BFA solution for 30-35 minutes prior to confocal microscopy.

Protein extraction and western blot analyses

Total protein samples were obtained from tobacco leaves in transient assays or from the leaves of transgenic *Arabidopsis*. Tobacco leaf samples were obtained from the leaf areas infiltrated with *Agrobacterium* expressing HopM1 fusions (i.e., these leaf areas were sprayed with 30 μM DEX solution with 0.01% Tween-20, and left at room temperature for 8 hours to allow protein expression). *Arabidopsis* leaf samples were obtained from the detached leaves which were dipped in DEX (30 μM) for 24 hours. Twenty mg of each leaf sample (fresh weight) was ground in 200 μl SDS buffer [100 mM Tris-HCl pH 6.8, 200 mM DTT, 4% SDS, 20% glycerol] for protein extraction. Extracts were immediately heated at 90°C for 10 minutes and then frozen at -20°C.

Prior to loading of each protein sample on a protein gel, extracts were thawed on ice, heated at 90°C for 3 minutes, and centrifuged at $10,000 \times g$ for 1 minute. Ten to

twenty μL of each sample was used for SDS-PAGE (equal volumes were used in a given gel). Total proteins were separated on precast gradient gels (4-20%, ISC BioExpress) or hand-made SDS-PAGE gels (7.5, 10, or 12% gels), then transferred onto Immobilon-P membrane (Millipore, Billerica, MA) using a semi-dry transfer apparatus (SEMIPHOR, Hoefer Scientific Instruments, San Francisco, CA). Immunoblot analyses were performed using a HopM1-specific antibody (Nomura et al., 2006) or a GFP-specific antibody (Santa Cruz Biotechnology, Inc., Santa Cruz, CA). For estimating the sizes of proteins, PageRuler™ Prestained Protein Ladder Plus (#SM1811, Fermentas International Inc, Ontario, Canada) was used.

RESULTS

Transiently expressed full-length HopM1 fusion proteins induce tissue death in tobacco leaves

Agrobacterium strains containing pBD derivatives designed to express the

HopM1-GFP or YFP-HopM1 fusion were hand-infiltrated into the leaves of *Nicotiana*

benthamiana or *Nicotiana tabacum*. After 48 hours, the transgenes were sprayed with 30

µM DEX. The infiltrated areas of tobacco leaves started losing turgor approximately 8

hours after DEX induction. Two days after DEX spray, the infiltrated area died. This was

similar to a previous report of tissue death induced by another TTSS effector of *Pst*

DC3000, AvrE, in tobacco (Badel et al., 2006). To confirm that the tissue death was

caused by the HopM1 fusion proteins, the transient assay was repeated with following

controls: *Agrobacterium* C58C1 alone, C58C1 carrying pBD vector, C58C1 carrying the

sGFP ORF in pBD, and C58C1 with the *hopM1* ORF in pTA7002 (another DEX-

inducible vector which carries a hygromicyn resistance gene [DebRoy et al., 2004;

Nomura et al., 2006]). These strains were hand-infiltrated into the leaves of *Nicotiana*

benthamiana or *Nicotiana tabacum*, and sprayed with 30 µM DEX. Two days after DEX

spray, only the areas injected with *Agrobacterium* carrying pTA7002-*hopM1*, pBD-

HopM1-GFP or pBD-YFP-HopM1 showed tissue death. C58C1, C58C1 carrying pBD

vector and C58C1 carrying pBD-sGFP did not show tissue death, and the appearance of

the infiltrated areas was indistinguishable from the uninfiltrated areas (Figure 2-2).

The fusion constructs of truncated *hopM1* were also transiently expressed in

tobacco leaves. In contrast to HopM1-GFP or YFP-HopM1, none of the truncated

(A) *N.benthamiana* leaves which were infiltrated with nothing, *Agrobacterium* C58C1, C58C1 transformed with pBD vector, C58C1 with sGFP ORF in pBD vector, C58C1 with 6xHis-HopM1 in pTA7002 (DebRoy et al., 2004; Nomura et al., 2006). (B) *N.benthamiana* leaves which were infiltrated with *Agrobacterium* carrying pBD derivatives designed to express HopM1 (full-length or truncated) fused with GFP or YFP ORFs under the DEX-inducible promoter. Black lines in the photos of pTA7002-6xHis-HopM1, pBD-HopM1-GFP and pBD-YFP-HopM1 mark the *Agrobacterium*-infiltrated area. Leaves were sprayed with 30 µM DEX solution and left at the room temperature for 48 hours prior to photography.

HopM1 fusions induced tissue death (Figure 2-2B). Therefore, only full-length HopM1 or HopM1 fusions were able to induce tissue death in tobacco plants.

Western blot analyses of HopM1 fusions in transient assay

The expression of the fusion proteins of full-length HopM1 or truncated HopM1 in transient assays was analyzed by immunoblot. Several controls were included: *N.tabacum* leaf sample without bacterial infiltration, pEGAD-eGFP for constitutive expression of eGFP and pTA7002-6XHis-HopM1 for DEX-inducible expression of HopM1. Immunoblotting was performed with an anti-HopM1 antibody or anti-GFP antibody (Figure 2-3). The results showed approximately expected sizes of each HopM1 fusion (HopM1-GFP: 102 kDa, YFP-HopM1: 102 kDa, HopM1-N-GFP: 59 kDa, YFP-HopM1-C: 72 kDa), except that the expression of YFP-HopM1-N was too low to detect. The gel lanes of HopM1-N-GFP (Figure 2-3B, lane 6) and YFP-HopM1-N (Figure 2-3B, lane 7) had faint bands of the approximate size of GFP detected by GFP antibody.

Transiently expressed fusions of full-length HopM1 are found in small, punctate structures in tobacco cells

To determine the localization of full-length HopM1 in plant cells, HopM1-GFP and YFP-HopM1 were transiently expressed in tobacco plants. After 8 hours of DEX induction (on average), some leaf tissue began to lose turgor, leading to tissue death eventually. Based on this observation, DEX induction time for preparing confocal microscope samples did not exceed 6 hours. Confocal microscopy was performed between 4 and 6 hours after DEX spraying. Both epidermal cells and mesophyll cells of tobacco plants were

Figure 2-3. Immunoblot analyses of HopM1 fusions in transient assays in *N.tabacum*, using (A) the anti-HopM1 antibody, and (B) the anti-GFP antibody. M: protein size markers. Lane 1 to 8 represent *N.tabacum* leaf samples infiltrated with *Agrobacterium* containing the following plasmids: lane 1, leaf sample without bacterial infiltration; lane 2, pEGAD; lane 3, pTA7002-6xHis-HopM1; lane 4, pBD-HopM1-GFP; lane 5, pBD-YFP-HopM1; lane 6, pBD-HopM1-N-GFP; lane 7, pBD-YFP-HopM1-N; lane 8, pBD-YFP-HopM1-C. All leaf samples were collected after 8 hour of DEX induction with 30 M of DEX solution. None of the leaf samples were observed by confocal microscopy to confirm the expression of proteins prior to sample preparation.

(A)
(B)
examined, but the majority of images were from epidermal cells.

Neither HopM1-GFP (Figure 2-4A and B) nor YFP-HopM1 (Figure 2-4C) was found in the plasma membrane or large organelles such as the chloroplast, nucleus, endoplasmic reticulum (ER), or vacuole. Instead, both HopM1-GFP (Figure 2-4A and B) and YFP-HopM1 (Figure 2-4C) were found in small, punctate structures in the cell. These punctate structures were not concentrated in specific areas of a cell, but they were not evenly dispersed in the cell, either. These structures actively moved in the cells. The images of HopM1-GFP and YFP-HopM1 looked similar, therefore the N-terminal or C-terminal fusion of fluorescence protein tagging did not seem to affect the localization of HopM1 fusion proteins.

To determine the localization of HopM1 at the earliest detectable stage, the condition of DEX-induction was modified in some experiments: 30 μM DEX solution was dabbed onto the surface of tobacco leaves without surfactant Tween-20, and the confocal microscopic observation was limited within 5 hours after DEX induction. The fluorescence from full-length HopM1 fusions could be observed 3 hours after DEX application (Christy Mecey and Sheng Yang He, unpublished). Full-length HopM1 fusion proteins were again found in small, punctate structures as well, although the density of punctate structures was lower than that observed with longer DEX treatment (Figure 2-4D: Christy Mecey and Sheng Yang He, unpublished). These punctate structures were more even in size and shape (Figure 2-4D), compared to the punctate structures observed 5 hours after DEX treatment (Figure 2-4A, B and C). According to the observations made at different time points of DEX treatment, I conclude that the fluorescence intensity and signal density of the punctate structures associated with full-length HopM1 fusion

proteins increased over time. The movement of punctate structures was almost stopped approximately 7 hours after DEX application.

Dual localization tests of full-length HopM1 fusions with a Golgi marker with or without Brefeldin A (BFA)

The localization of full-length HopM1 fusions further was investigated by dual localization tests with different subcellular marker proteins that are associated with small organelles. First, I examined the possibility that HopM1-GFP may be localized to the Golgi apparatus. The rat sialyl transferase (Wee et al., 1998; Saint-Jore et al., 2002) fused to RFP (ST-RFP: the gift from Dr. Federica Brandizzi laboratory, Michigan State University, East Lansing, MI) was selected as a marker for this purpose. ST-RFP was transiently co-expressed with HopM1-GFP or YFP-HopM1 in tobacco leaves, and confocal microscopy analyses were performed both at early time points (within 5 hours) and later time points (after 5 hours) after the DEX-induction. In both condirions, there was no significant co-localization of full-length HopM1 fusions (Figure 2-5). At later time point, punctate structures associated with HopM1 fusion protein (HopM1-GFP) and ST-RFP showed distinct sizes, densities and distributions in the cells (Figure 2-5).

Fungal toxin Brefeldin A (BFA) was also tested to further investigate the relationship between the localization of HopM1-GFP and Golgi, based on the known effects of BFA on disruption of Golgi stacks and fusion of Golgi into ER (Brandizzi et al., 2002; Ritzenthaler et al., 2002; Saint-Jore et al., 2002). The BFA solution was applied to the leaf samples 5-6 hours after the leaves were co-infiltrated with *Agrobacterium* strains carrying pBD-HopM1-GFP and/or pVKH-ST-RFP. As expected, ST-RFP-associated

58

Figure 2-5. Dual localization results of full-length HopM1 fusion proteins and ST-RFP. The fluorescence from HopM1-GFP (A), ST-RFP (B) and their merged image (C) within 5 hours after DEX treatment; the fluorescence from YFP-HopM1 (D), ST-RFP (E) and their merged image (F) 5 hours after DEX treatment. Images A, B and C were from the leaf sample which was dabbed with DEX solution without Tween-20. Image D, E and F were from the leaf sample which was sprayed with DEX solution containing 0.01% Tween-20. HopM1-associated punctate structures are green (A, C, D and F) and ST-RFP are red (B, C, E and F). YFP-HopM1 in panel A and ST-RFP in panel B are indicated with red arrows and white arrows, respectively. A, B and C are from Z-stack, and D, E and F are from single focal planes of the epidermal cell layer of *N.tabacum.*, respectively
punctate structures disappeared and fluorescence was changed into a mesh-like network

(Figure 2-6), reflecting the re-distribution of ST-RFP into the ER by BFA (Brandizzi et

al., 2002; Saint-Jore et al., 2002). Contrary to this change, HopM1-GFP did not disappear,

and there was no significant morphological change of the punctate structures associated

with HopM1-GFP (Figure 2-6).

Dual localization tests of YFP-HopM1 and endosome markers

Besides Golgi, endosomal compartments were selected for determining the

localization of HopM1 fusions. Endosome is a collection of small, vesicular organelles

the main function of which is to transport and sort cargo materials between Golgi,

vacuole and plasma membrane (Jürgens and Geldner, 2002; Bassham et al., 2008:

Robinson et al., 2008). The endosomes are shown as small, punctate structures (Ueda et

al., 2001: Ueda et al., 2004: daSilva et al., 2006; Dettmer et al., 2006). In eukaryotic cells

several different types of endosomes exist: they are different in structure, function and

biochemical composition (Bassham et al., 2008). There are three known subgroups of

endosomes (Robinson et al., 2008; Otegui and Spitzer, 2008): early endosome, late

endosome and recycling endosome. Early endosomes are produced from endocytosis of

the plasma membrane. In plants, trans-Golgi network (TGN) is considered to be early

endosomes (Dettmer et al., 2006: Lam et al., 2007). Late endosomes function in the

vesicle trafficking from early endosomes to the vacuole, and include distinctive structures

such as multivesicular bodies (MVB) or prevacuolar compartment (PVC) (Otegui and

Spitzer, 2008: Robinson et al., 2008). Recycling endosomes are thought to function from

early and late endosomes to the plasma membrane (Otegui and Spitzer, 2008: Robinson
Figure 2-6. Dual localization result of HopM1-GFP and ST-RFP with BFA treatment. HopM1-GFP (A), ST-RFP (B) and their merged image (C) are shown. The induction of HopM1-GFP was by spraying of DEX solution with 0.01% of Tween-20. All images are from single focal planes of the epidermal cell layer of *N.tabacum*, 5-6 hours after DEX treatment. Ch: chloroplast.

et al., 2008). Currently known endosome markers area available both for different types of endosomes and/or for different portions of an endosome subgroup (Otegui and Spitzer, 2008: Robert et al., 2008; Robinson et al., 2008).

VHA-a1, a marker for TGN, was selected first for dual localization with HopM1 fusion proteins. Tanaka et al (2009) recently showed that AtMIN7, a member of *Arabidopsis* ARF-GEF family and a cellular target of HopM1 (Nomura et al., 2006), is co-localized with VHA-a1. Moreover, like HopM1-GFP observed in this study, the localization of VHA-a1-GFP does not show significant change upon BFA treatment, although some aggregation was noted (Dettmer et al., 2006). YFP-HopM1 and VHA-a1-RFP (Dettmer et al., 2006) were transiently co-expressed in tobacco leaves, and the expression of YFP-HopM1 was induced by DEX for 3 or 4 hours. The confocal microscopy result showed that YFP-HopM1 and VHA-a1-RFP were largely co-localized (Figure 2-7: Christy Mecey and Sheng Yang He, unpublished). Next, *Arabidopsis* RabF1 (ARA6), another early endosome marker (Ueda et al., 2001; Kotzer et al., 2004; Haas et al., 2007), was selected in co-localization study. The confocal microscopic observation was performed at early time points (before 5 hours) and later time points (after 5 hours) after the DEX-induction of YFP-HopM1. YFP-HopM1 and ARA6-CFP were co-localized at earlier time points (Figure 2-8: Christy Mecey and Sheng Yang He, unpublished), but they did not co-localize at later time point (Figure 2-8).

Localization of truncated HopM1 fusion proteins

Next, the localization of truncated HopM1 protiens fused to GFP or YFP was studied: the truncated HopM1 proteins included HopM1-N-GFP, YFP-HopM1-N, and
Figure 2-7. Dual localization results of YFP-HopM1 and VHA-a1-RFP. The fluorescence from YFP-HopM1 (indicated with red arrows) (A), VHA-a1-RFP (indicated with white arrows) (B) and their merged image (co-localized punctate structures are marked with blue arrows) (C) within 5 hours after dabbing DEX solution on the leaf surface. All of the images are from Z-stack, from the epidermal cell layer of *N.tabacum*.

Figure 2-8. Dual localization results of YFP-HopM1 and ARA6-CFP. The fluorescence from YFP-HopM1 (A), ARA6-CFP (B) and their merged image (C) within 5 hours after DEX treatment; the fluorescence from YFP-HopM1 (D), ARA6-CFP (E) and their merged image (F) 5 hours after DEX treatment. Images A, B and C were from the leaf sample which was dabbed with DEX solution without Tween-20. Image D, E and F were from the leaf sample which was sprayed with DEX solution containing 0.01% Tween-20. YFP-HopM1-associated punctate structures are yellow (A, C, D and F) and ARA6-CFP are blue (B, C, E and F). YFP-HopM1 in panel A and ARA6-CFP in panel B are indicated with green arrows and red arrows, respectively. Co-localized YFP-HopM1 and ARA6-CFP are marked with blue arrows (C).All images are from single focal planes of the epidermal cell layer of *N.tabacum*.
YFP-HopM1-C (HopM1-C-GFP was excluded from localization study due to mutations introduced during cloning). The confocal microscopic observations were performed at both early time point (within 5 hours) and later time point (between 5 and 6 hours) after DEX-induction. At early time point, HopM1-N-GFP and YFP-HopM1-N were found in small, punctate structures, which were similar to those observed with full-length HopM1 fusion proteins. YFP-HopM1-C was shown in unidentified structures which were round with uneven size (Figure 2-9). In later time point, however, all truncated HopM1 fusion proteins were found dispersed in the cells, instead of punctate structures (Figure 2-9).

The localization of the N-terminus of HopM1 was further studied. The shape and size of the punctate structures of YFP-HopM1-N at the early time point were similar to those of full-length HopM1 fusion proteins. This result suggested that YFP-HopM1-N might be localized in the same subcellular structures in which full-length HopM1 fusions are localized. To test this possibility, YFP-HopM1-N was co-expressed with VHA-a1-RFP into tobacco leaves, which were examined by confocal microscopy. As shown in Figure 2-10, YFP-HopM1-N and VHA-a1-RFP co-localized, indicating that YFP-HopM1-N is localized in TGN. This result provides evidence that the N-terminal 300 amino acids of HopM1 contain all the information for localization to TGN.

Transgenic expression of HopM1 fusions in *Arabidopsis*

HopM1 fusions which were constructed and examined by confocal microscopy in transient assays were transformed into *Arabidopsis* by floral dipping (Clough and Bent, 1998), to establish stable transgenic *Arabidopsis* plants. The T_1 plants of each HopM1 fusion were sprayed with BASTA solution. Surviving plants were obtained from T_1 seeds

Figure 2-9. Localization of truncated HopM1 fusion proteins. The fluorescence from (A) HopM1-N-GFP at early time point (marked with red aqrrows); (B) YFP-HopM1-C at early time point (marked with blue arrows); (C) HopM1-N-GFP at later time point; (D) YFP-HopM1-N at later time point; (E) YFP-HopM1-C at later timer point. All images are from single focal planes. Panels A and B are from the leaf samples which were dabbed with DEX solution and examined within 5 hours. Panels C, D, and E are from the leaf samples which were sprayed with DEX solution with 0.01% Tween-20 and observed 5 hours after DEX induction. S: Stomate. Ch:chloroplast. G: guard cell.

fluorescence from YFP-HopM1-N (indicated with white arrows) (A), VHA-a1-RFP
(indicated with green arrows) (B) and their merged image (co-localized punctate
structures are marked with blue arrows) (C) within 5 hours after dabbing DEX solution
on the leaf surface. All of the images are from Z-stack, from the epidermal cell layer of
N.tabacum.
for four constructs in Col-0 background (Table 2-4). One leaf of each plant was detached, dipped in DEX solution, and examined by confocal microscopy after 24 hours (Table 2-4; Figure 2-11A-D). Full-length HopM1 fusions were found in punctate structures, and truncated HopM1 fusion proteins were shown dispersed in the cell (Figure 2-11A-D). These localization patterns were consistent with those in transient assay conducted at later time point after DEX treatment (Figure 2-4 and 2-9). The HopM1 constructs were transformed into the *atmin7* mutant, and the T_1 plants transformed with YFP-HopM1 and YFP-HopM1-N were obtained. YFP-HopM1 in the *atmin7* background was examined by confocal microscopy (Figure 2-11E); it was shown in small, punctate structures, which were similar to those in Col-0 background.

Table 2-4. Summary of transgenic *Arabidopsis* expressing HopM1 fusions.

HopM1 fusion name	*Arabidopsis* background	Line number
HopM1-GFP	Col-0	#1*,11, 12
YFP-HopM1	Col-0	#2*,3,6
HopM1-N-GFP	Col-0	#1*,3
YFP-HopM1-N	Col-0	#4*,10
YFP-HopM1	*atmin7*	#3*
YFP-HopM1-N	*atmin7*	#100, 101, 102, 103, 104

* indicates the transgenic lines which were examined by confocal microscopy (Figure 2-11)

Figure 2-11. HopM1 fusion proteins in *Arabidopsis* (Col-0 and *atmin7* background). The fluorescence of (A) HopM1-GFP in Col-0 (line#1), (B) YFP-HopM1 in Col-0 (line#2), (C) HopM1-N-GFP in Col-0 (line#1), (D) YFP-HopM1-N in Col-0 (line#4), and (E) YFP-HopM1 in *atmin7* (line#3). All images are from single focal planes of leaf samples except A, which was from z-stack. Leaf samples were dipped in DEX solution for 24 hours prior to confocal microscopy.
DISCUSSION

To determine the subcellular localization of HopM1 in plant cells, full-length and truncated versions of HopM1 were fused with selected fluorescence protein tags (sGFP and EYFP), and they were analyzed using transient expression assays in tobacco leaves and stable expression in *Arabidopsis* plants. All HopM1 fusions were induced by DEX. Under this condition, the expression of all HopM1 fusions can be regulated based on the induction time and DEX concentration.

When full-length HopM1 fusions (HopM1-GFP and YFP-HopM1) were transiently expressed in tobacco, the leaf tissues began to lose turgor approximately 8 hours after DEX induction, and were dead 48 hours after DEX induction. Tissue death was also induced by 6xHis-HopM1 expressed from pTA7002-6xHis-HopM1. The tissue death induced by HopM1 in *Arabidopsis* was previously reported (DebRoy et al., 2004; Nomura et al., 2006), but the tissue death induction by HopM1 (and HopM1 fusions) in a nonhost plant (tobacco) has not been reported before this study. The characteristics of the tissue death in tobacco plants induced by 6xHis-HopM1, HopM1-GFP and YFP-HopM1 are not clearly defined in this study. Badel et al. (2006) showed that another TTSS effector, AvrE, induced tissue death in *N.tabacum*. AvrE-induced tissue death was interpreted as a kind of nonhost hypersensitive response (HR), but experiments for determining the molecular characteristics of the tissue death were not performed (Badel et al., 2006). Considering that AvrE and HopM1 are both encoded in the CEL of *Pst* DC3000 and that they have redundancy in function (DebRoy et al., 2004), it is possible that the tissue death induced by AvrE and HopM1 (or HopM1 fusion proteins) share the

similar mechanism in tobacco plants. The tissue death caused by DEX-induced HopM1-GFP or YFP-HopM1 limited the DEX-induction time for confocal microscopy and protein sampling for immunoblot analyses. In this thesis, the confocal microscopy was performed within 6 hours after DEX spray, and protein sampling for western blot analysis was done 8 hours after DEX induction.

Confocal microscopy in this study was performed at two different time points: an early time point which was between 3 hours and 4 hours after DEX-induction, and a later time point which was between 4 hours and 6 hours after DEX-induction. In the experiments at later time point, the DEX solution was sprayed onto the leaf surface, and the surfactant Tween 20 (0.01%) was added for enhanced uptake of DEX. Under this condition, the GFP or YFP signal of full-length or truncated HopM1 fusion proteins was intense, clearly distinguishable from the background. The density of the fluorescence of full-length HopM1 fusion was high as well. Because it is generally believed that bacteria deliver only small amounts of effectors into host cells, it would be ideal to express effectors at the lowest possible level that still allow microscopic observation. Therefore, in some experiments, the observation was performed between 3 hours and 5 hours after DEX application, and the DEX was dabbed onto the leaf surface without Tween-20. Under this condition the intensity and density of the GFP/YFP fluorescence were reduced compared to those obtained at later time point, but they were distinguished from the background signal.

Full-length HopM1 fusion proteins were found in small, punctate structures both in early and later time points. However, in later time point the density and intensity of GFP/YFP signal were higher than those in earlier time point. It is likely that, within the

time periods used in this study, the expression of full-length HopM1 fusion proteins is proportional to the DEX exposure time. The difference in DEX concentration between dabbing and spraying (with or without Tween-20, respectively) also could affect the expression of HopM1 fusions.

The dual localization experiments show that YFP-HopM1 co-localizes with VHA-a1-RFP (a marker for TGN) and ARA6-CFP (a marker for early endosome). The localization of HopM1 in TGN is similar to that of AtMIN7 (Tanaka et al., 2009), consistent with the previous report that HopM1 interacts with AtMIN7 (Nomura et al., 2006). This result also is consistent with the notion that HopM1 targets and interferes with vesicle trafficking to suppress host defenses. On the other hand, HopM1-GFP did not co-localize with ST-RFP (a Golgi marker) and did not relocalize after BFA treatment as ST-RFP did. These results indicate that HopM1 does not target Golgi apparatus for its function. Finally, the dual localization assay of HopM1-GFP and PTS1-dsRED2 (a marker for peroxisome: Gould et al., 1989; Reumann, 2004; Fan et al., 2005) showed that HopM1 is not localized to the peroxisome (Appendix 2-1).

Besides full-length HopM1 fusions, the localization of truncated HopM1 fusions (HopM1-N-GFP, YFP-HopM1-N and YFP-HopM1-C) was also studied. These truncated HopM1 fusion proteins did not induce tissue death in tobacco plants, which is correlated with a lack of virulence function of HopM1$_{1-300}$ and HopM1 $_{301-712}$ in Arabidopsis. The localization of truncated HopM1 fusion proteins provides interesting information. At early time point of DEX treatment, the N-terminus (YFP-HopM1-N) was localized in small, punctate structures, whereas the C-terminus (YFP-HopM1-C) was found in bigger, irregular-sized structures. YFP-HopM1-N co-localized with VHA-a1-RFP and ARA-

CFP, indicating that the N-terminus of HopM1 is sufficient for the localization to the

same endosomal compartments in which full-length HopM1 fusion protein is localized.

In a previous study to determine the intramolecular regions important for the virulence

function of HopM1, transgenic overexpression of the same N-terminus of HopM1 had a

dominant-negative effect on full-length HopM1 delivered from bacteria during infection,

suppressing the symptom development and multiplication of the ΔCEL mutant

complemented with a HopM1-expressing plasmid (Nomura et al., 2006). It was suggested

that the N-terminus of HopM1 might function as an independent domain, interfering with

the virulence function of the full-length HopM1 in plant cells (Nomura et al., 2006). The

same localization of the N-terminus of HopM1 and full-length HopM1 in the endosomal

compartments suggests that the dominant-negative effect may be caused in part by

competition for the same localization between the overexpressed, nonfunctional N-

terminus of HopM1 and full-length, functional HopM1.

At later time point of DEX- treatment, the intensity and density of the

fluorescence signal of full-length HopM1 fusion proteins increased, and the shape of the

punctate structures of full-length HopM1 proteins became more irregular compared with

that at early time point of DEX treatment. Dual localization with a Golgi marker suggests

that full length HopM1 was not in the Golgi apparatus at later time points, but the precise

location was not precisely determined. It is possible that increased expression of full-

length HopM1 fusion proteins led to mislocalization to additional small organelles.

Alternatively, the high-density punctate structures at the later time point were caused by

the virulence action of full-length HopM1 in plant cells. In this case, by degrading

AtMIN7, HopM1 might have induced abnormal structures from endosomal

compartments. The punctate structures were found both in the transient expression assays and in transgenic *Arabidopsis* plants, suggesting that the effect of HopM1 upon the endomembrane structures is similar in nonhost and host plants. This putative distortion of endomembrane structures could be related to the suppression of basal defense of *Arabidopsis* by HopM1 (DebRoy et al., 2004; Nomura et al., 2006).

The different localization patterns between early and later time points were more obvious for the fusion proteins of truncated HopM1: at later time point both the N-terminus and C-terminus of HopM1 were dispersed in the cell. The dispersed localization of truncated HopM1 fusion proteins is similar to that of GFP alone (Appendix 2-2), but this diffused localization is not likely caused by fortuitous degradation of fusion proteins, which could generate a free GFP or YFP tag: western blot analysis did not indicate a significant amount of GFP or YFP. Thus, it seems that the localization of the N-terminus of HopM1 in the endosomal compartments is transient, and that neither the N-terminus nor the C-terminus of HopM1 is sufficient for the long-term localization in the endosome.

The HopM1 fusions were transformed into *Arabidopsis* (Col-0 and *atmin7)* for establishing transgenic *Arabidopsis* plants. DEX-induction time was longer in *Arabidopsis* (up to 24 hours) than in tobacco, because the expression of HopM1 fusions was slower in *Arabidopsis*: for example, confocal microscopic examination of transgenic plants expressing HopM1-GFP in Col-0 showed that, between 4-6 hours after DEX induction, full-length HopM1 fusion was not detected. At least 8 hours were needed for detecting fluorescence above background, and at 24 hours after DEX induction the fluorescence was clearer. The localization patterns of various HopM1 fusions in transgenic *Arabidopsis* were consistent with those in transient assays with tobacco at later

time point of DEX treatment: HopM1-GFP and YFP-HopM1 were associated with small, punctate structures, whereas HopM1-N-GFP and YFP-HopM1-N were dispersed in *Arabidopsis* cells.

The transgenic *Arabidopsis* plants expressing full-length or truncated HopM1 fusion proteins need to be further characterized. First, it would be important to confirm tissue death of transgenic *Arabidopsis* plants expressing HopM1-GFP or YFP-HopM1 after DEX induction: this experiment is needed to determine whether full-length HopM1 fusion proteins act like untagged HopM1, which induces tissue death in *Arabidopsis* (Nomura et al., 2006). Second, the localization of the HopM1 fusion proteins should be determined at early time point and with a reduced DEX concentration to avoid potential problems associated with overexpression of fusion proteins.

CHAPTER 3

Studies of the roles of several *Arabidopsis* ARF-GEFs in the defense against bacteria and their interaction with HopM1

Kinya Nomura contributed to Figure 3-9.

ACKNOWLEDMENTS

ABSTRACT

AtMIN7, an adenosine-diphosphate ribosylation factor-guanine nucleotide-exchange factors (ARF-GEF) gene of *Arabidopsis*, has a role in defense against the ΔCEL mutant of *Pst* DC3000. AtMIN7 interacts with N-terminus of HopM1 (HopM1$_{1-300}$) and it is degraded by full-length HopM1. In addition to *AtMIN7*, there are seven more *ARF-GEF* genes in *Arabidopsis*. To determine whether any of these genes have a role in defense, the multiplication of the ΔCEL mutant was quantified in the T-DNA inserton lines, and the yeast two-hybrid system was used for testing the interactions between HopM1 and these ARF-GEFs.

I was able to obtain T-DNA insertion lines for three of the seven ARF-GEF genes, *BIG2, BIG3* and *BIG4*. The T-DNA insertion mutants of *BIG2* (salk_033446) and *BIG4* (salk_082249) were knockouts, and the *BIG3* (salk_044617) insertion line was a knock-down. Unlike *atmin7* plants the multiplication of the ΔCEL mutant in these T-DNA insertion mutants was not significantly higher than wild type *Arabidopsis* (Col-0), suggesting that none of the three genes have significant role in the defense against the ΔCEL mutant as *AtMIN7* did.

The C-terminal portions of four ARF-GEFs (BIG1, BIG3, GNL1 and GNL2) were studied by yeast two-hybrid assay to determine whether they interacted with HopM1$_{1-300}$. The C-terminus of GNL2 did not interact with HopM1$_{1-300}$. The interactions between HopM1$_{1-300}$ and the C-termini of BIG1, BIG3 and GNL1 were not determined because of the failure to express the proteins in yeast.

INTRODUCTION

Previous research results showed that twenty one *Arabidopsis* proteins interact

with the first 300 amino acids of the TTSS effector HopM1 from the bacterial pathogen

Pseudomonas syringae pv. *tomato* (*Pst*) DC3000. These proteins were named AtMINs

(*Arabidopsis thaliana* HopM1 interactors). At least eight AtMINs were destabilized by

full-length HopM1 in plants and in yeast. Among them, *AtMIN7* was shown to be

important for *Arabidopsis* defense against the ΔCEL mutant of *Pst* DC3000 (Nomura et

al., 2006). In the ΔCEL mutant the conserved effector locus (CEL), encoding HopM1 and

three other effectors, is deleted. As a result, the ΔCEL mutant does not cause symptoms

and its multiplication level is reduced in host plants (Alfano et al., 2000; Badel et al.,

2003; DebRoy et al., 2004). In the *atmin7* plants, however, the multiplication of the

ΔCEL mutant is increased and the symptom development is partially restored (Nomura et

al., 2006). In addition, the *atmin7* mutant the ΔCEL mutant is compromised in callose

deposition (a defense response) after the inoculation of the ΔCEL mutant compared with

wild-type Col-0 plants (Nomura et al., 2006).

AtMIN7 is one of the eight members of *Arabidopsis* gene family encoding

adenosine-diphosphate ribosylation factor-guanine nucleotide-exchange factors (ARF-

GEFs: Anders and Jürgens, 2008; Figure 3-1). ARF-GEFs regulate adenosine-

diphosphate ribosylation factor (ARF) GTPase by promoting nucleotide exchange from

its inactive GDP-bound state to the active GTP-bound state. It has been shown that ARF-

GTPases function in vesicle budding necessary for intracellular vesicle trafficking, and

ARF-GEF-dependent activation of ARF is critical for promoting the vesicle formation
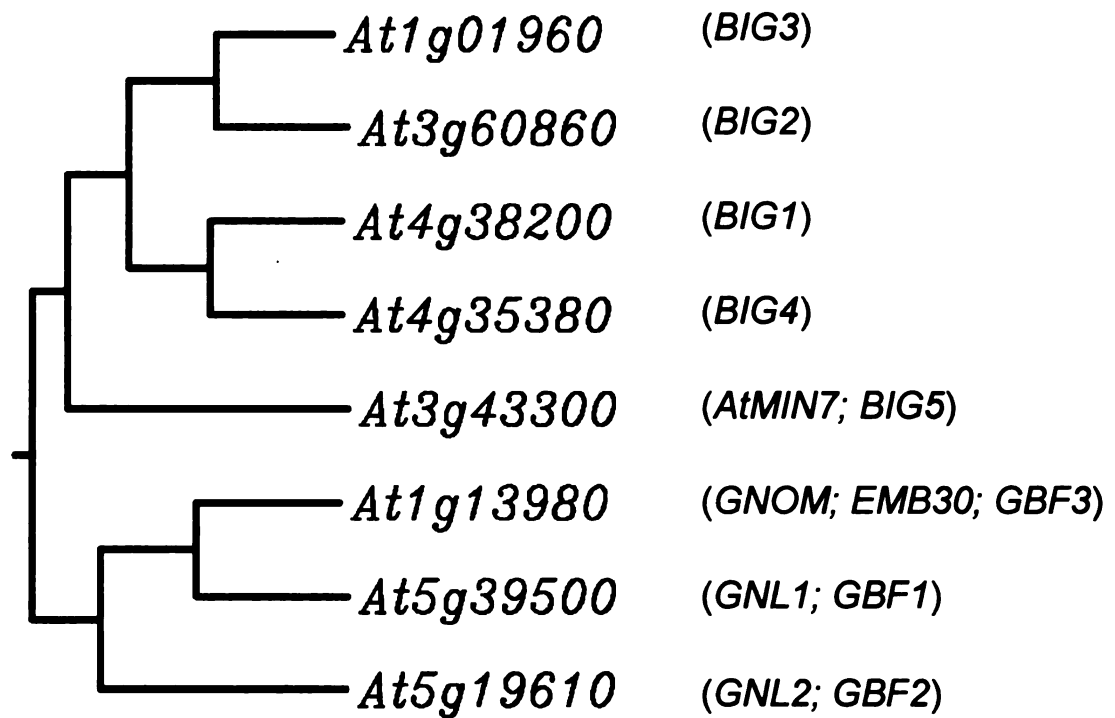

Figure 3-1. A phylogenetic tree of *Arabidopsis ARF-GEF* genes with their names in parenthesis (modified from Nomura et al., 2006).

and budding in trafficking pathways (Memon, 2004; Gillingham and Munro, 2007; Casanova, 2007; Anders and Jürgens, 2008; Bassham et al., 2008). ARF-GEF proteins share a conserved Sec7 domain that is sufficient to catalyze GTP/GDP exchange on ARFs (Chardin et al., 1996; Jackson and Casanova, 2000; Gillingham and Munro, 2007). The Sec7 domains of some ARF-GEFs are sensitive to a fungal toxin Brefeldin A (BFA). BFA binds to the ARF-GDP complex and interferes with the exchange of GTP for GDP (Anders and Jürgens, 2008).

The eight *ARF-GEF* genes including *AtMIN7* are grouped into two subfamilies: Sec7/BIG-type and Gea/GNOM/GBF-type (Cox et al., 2004; Gillingham and Munro, 2007). *AtMIN7* is in the Sec7/BIG-type subfamily. The *Arabidopsis ARF-GEF* genes are closely clustered in a larger phylogenetic tree containing all ARF-GEF genes, and their Sec7 domains show highly similarity (Cox et al., 2004). Currently, *AtMIN7* is the only *ARF-GEF* gene which has been studied in plant-pathogen interactions. Two other *ARF-GEF* genes have been characterized in growth and development of *Arabidopsis*: GNOM (Steinmann et al., 1999; Geldner et al., 2003), and GNOM-LIKE 1 (GNL1: Richter et al., 2007; Teh and Moore, 2007). GNOM is found in endosome/prevacuolar compartments (PVCs) of the *Arabidopsis* cells, and it is involved in the polarized targeting of PIN1 which is critical for polar auxin transport (Steinmann et al., 1999; Geldner et al., 2003). GNL1 is detected in the Golgi stack and has overlapping cellular functions with GNOM (Richter et al., 2007; Teh and Moore, 2007).

Although the multiplication of the ΔCEL mutant is higher in *atmin7* mutant plants compared with that in wild-type Col-0 plants, it does not reach the level of *Pst* DC3000 growth in *Arabidopsis*, suggesting that AtMIN7 is not the only host target of HopM1

(Nomura et al., 2006). Second, in preliminary experiments the product of another *ARF-GEF* encoding gene (*AtBIG2* [Cox et al., 2004]) had a weak yeast two-hybrid interaction with HopM1 (Kinya Nomura and Sheng Yang He, unpublished). Third, BFA treatment of *Arabidopsis* Col-0 leaves restored the multiplication of the ΔCEL mutant to the level of *Pst* DC3000, indicating that there are other host targets of HopM1 which are BFA-sensitive, possibly including additional ARF-GEFs (Nomura et al., 2006). These observations suggest that other ARF-GEFs may also have a role in the defense of *Arabidopsis* and their products may be targeted by HopM1.

Nomura et al. (2006) tested the C-termini of three *ARF-GEF* genes (*BIG2, BIG4* and *GNOM*) in yeast two-hybrid system with HopM1$_{1-300}$; none of them showed an interaction with HopM1$_{1-300}$. However, not all *Arabidopsis ARF-GEF* genes were tested. Additionally, no study has been reported to directly determine the role of individual *ARF-GEF* genes in *Arabidopsis* defense against the ΔCEL mutant.

In this chapter, *Arabidopsis ARF-GEF* genes that had not been previously studied were analyzed with two approaches. First, to determine a possible role of other *ARF-GEF* genes in *Arabidopsis* defense against the ΔCEL mutant, the growth of the ΔCEL mutant in the T-DNA insertion mutants of *ARF-GEF* genes were compared with that of *atmin7* plants. Second, yeast two-hybrid assays were performed to examine possible physical interactions between these ARF-GEFs with HopM1$_{1-300}$.

MATERIALS AND METHODS

Identification of homozygous T-DNA insertion mutants for *Arabidopsis ARF-GEF* genes

The T-DNA insertion mutant of *AtMIN7* (salk_012013) was previously characterized by Nomura et al. (2006) and it was used in this chapter. The genomic sequences and putative T-DNA insertions of the *ARF-GEF* mutants were examined in The *Arabidopsis* Information Resource (TAIR: www.arabidopsis.org), and the mutants with putative T-DNAs located in exons were selected (Table 3-1). The seeds of the selected T-DNA insertion mutants were purchased from *Arabidopsis* Biological Resource Center (ABRC, The Ohio State University, Columbus, OH).

Plants were grown in soil for 4-5 weeks. Genomic DNA was extracted from leaf tissue of each plant and prepared following the protocol provided with the SIGMA REDExtract-N-Amp™ Plant PCR kit (Sigma-Aldrich, St. Louis, MO). The primers for genomic PCR are summarized in Table 3-2. For each T-DNA insertion mutant, two pairs of primers were used. One pair consists of two gene-specific primers that are before and after the putative insertion site of T-DNA. The second primer set includes a gene-specific primer and the primer designed from the left border of the T-DNA (5'-GACCGCTTGCTGCAACTCTCTC-3'). The locations of the primers in each *ARF-GEF* gene sequence are shown in the appendix (Appendix 3-1 to 3-7). Ten microliters of each PCR product was run on a 1% agarose gel containing SYBR® Safe DNA gel stain (1:10,000 dilution: Invitrogen, Carlsbad, CA). Gels were photographed with Quantity One software (Bio-Rad Laboratories, Hercules, CA), and the images were processed with

Confirmation of gene knockout of T-DNA insertion mutants by reverse transcription and polymerase chain reaction (RT-PCR)

Homozygous T-DNA insertion mutants identified by PCR (salk_033446, salk_044617, and salk_082249) were analyzed by RT-PCR to confirm the loss of transcript. Total RNA sample of each salk line was extracted from 100 mg of *Arabidopsis* leaf tissue with the RNeasy® Plant Mini Kit (QIAGEN, Valencia, CA), followed by genomic DNA removal using RQ1 RNase-free DNaseI (Promega, Madison, WI). RNA was quantified with a NanoDrop ND-1000 Spectrophotometer (NanoDrop, Wilmington, DE).

RT-PCR was performed using the RNA LA PCR Kit (AMV), Ver. 1.1 (TaKaRa, Japan). The reverse transcription reaction mixture was prepared following the modified protocol of RNA LA PCR Kit (AMV), Ver. 1.1 (5mM $MgCl_2$, 1 × RNA PCR Buffer, 1 mM dNTP mixture, 1 unit/μl RNase Inhibitor, 0.25 units/μl AMV Reverse Transcriptase, 0.125 μM Oligo-dT Adaptor Primer, RNase-free water and 200-300 ng total RNA). The reverse transcription reaction was performed in a total volume of 50 μl, and incubated for 30 minutes at 45°C, followed by 5 minutes at 99°C and 5 minutes at 5°C. This cDNA sample was used as template in the PCR reaction with gene-specific primer pairs (Table 3-3). The sequences of these primers were chosen after the putative T-DNA insertion sites (Appendix 3-1 to 3-7). Each primer was checked by Basic Local Alignment Search Tool (BLAST: http://blast.ncbi.nlm.nih.gov/blast.cgi), to determine whether the primer shares sequence identity with an unrelated area of the *Arabidopsis* genome. Only the

Forward primer D3 for salk_033446 (*BIG2*, At3g60860)	5'-CGCCTGGCTCTACGAGACCT-3'
Reverse primer D3 for salk_033446 (*BIG2*, At3g60860)	5'-CTTGCATCTGTGTCATGGGTCCTAGC-3'

primers which showed identity only with the selected *ARF-GEF* gene were used for RT-PCR. The locations of the selected primers in each *ARF-GEF* gene sequence are shown in the appendix. RT-PCR was performed using *Arabidopsis ACT8* gene-specific primers as a control (Table 3-3).

The second PCR reaction contained 2.5 mM $MgCl_2$, 1 X LA PCR Buffer II, 0.2 μM of each primer, sterilized distilled water and 10 μl of the previous reverse transcription reaction sample in a final volume of 50 μl. The reaction was performed as follows: 94°C, 2 minutes (1 cycle), 94°C, 30 seconds, 53°C, 30 seconds, 72°C, 1 -2 minutes (25 cycles, 30 cycles, 40 cycles or 50 cycles) and 72°C, 10 minute (1 cycle). Ten μl of the PCR reactions were loaded on a 1% agarose gel containing SYBR® Safe DNA gel stain (1:10,000 dilution: Invitrogen, Carlsbad, CA). Gels were photographed with Quantity One software (Bio-Rad Laboratories, Hercules, CA), and the images were processed with Adobe Photoshop Element version 5.5 or 7.0.

Construction of *ARF-GEF* gene clones for yeast two-hybrid assays

Four *ARF-GEF* genes (*BIG1*, *BIG3*, *GNL1* and *GNL2*) were cloned for the yeast two-hybrid assay. The 3' ends downstream of the putative Sec7 domains were selected for cloning, following the cloning procedure of the 3' end of *AtMIN7* (Nomura et al., 2006): the sequences of the ORFs of four selected ARF-GEF genes were aligned with other *Arabidopsis ARF-GEF* genes by CLUSTALW (http://align.genome.jp/), and the putative Sec7 domain and the C-terminus after the Sec7 domain was determined in each ORF. The putative amino acid sequence of the C-terminus of each ARF-GEF is in Figure 3-2. The 3'ends were obtained by PCR with primers in Table 3-4. The diagrams of

ARF-GEF genes are in Figure 3-3. The genomic DNA or cDNA from *Arabidopsis* Col-0

ecotype was used as a template for PCR, depending on whether introns are present in the

region to be cloned (Table 3-4). Each PCR was performed with *PfuTurbo*® DNA

polymerase (Stratagene, La Jolla, CA). PCR products were subcloned into pB42AD-L

vector (pB42AD vector (Clontech, Mountain View, CA) with multicloning sites) and

sequenced. Mutation-free clones were transformed into yeast strain EGY48 p8oplacz

according to the manufacturer's protocol (frozen-EZ Yeast Transformation II™ kit,

Zymo Research Corperation, Orange, CA).

Yeast two-hybrid assay

Twenty µl of each yeast culture expressing $HopM1_{1-300}$ and the C-termini of *ARF-*

GEF genes or containing an empty vector (pBD42AD-L) were grown on the solid

SD+Glu-Ura-His-Trp medium (13.35g of minimal SD base, 0.35g of -Ura-His-Trp DO

supplement, 10g of Agar in 500 ml water: Clontech, Mountain View, CA) at 30 °C for

two days. A single colony of the each yeast was used to inoculate in 2 ml of SD+Glu-

Ura-His-Trp liquid medium (6.675g of minimal SD base, 0.175g of -Ura-His-Trp DO

supplement in 250 ml water: Clontech, Mountain View, CA) and cultured at 30 °C with

shaking for approximately 24 hours. One mililiter of this liquid culture was used to

inoculate into 6 ml of SD+Glu-Ura-His-Trp liquid medium, and re-cultured overnight (20

µl of each culture was spotted on the SD+Glu-Ura-His-Trp solid medium again, and

incubated at 30 °C for two days). One ml of each culture was collected and centrifuged at

the room temperature for 4 minutes at 500xg. The pellet was washed with 10 ml of Tris-

EDTA buffer. The washed pellet was resuspended with 6 ml of SD+Gal-Ura-His-Trp
Figure 3-3. Diagrams of four *ARF-GEF* genes analyzed by yeast two-hybrid assay. Green box with S denotes the putative Sec7 domain of each gene. liquid medium (9.25g of minimal SD base Gal/Raf and 0.175g of -Ura-His-Trp

supplement in 250 ml water: Clontech, Mountain View, CA), and 20 µl of each

resuspended sample was spotted on the SD+Gal-Ura-His-Trp solid medium containing

X-gal and BU salts (9.25g or minimal SD base Gal/Raf, 0.175g of -Ura-His-Trp DO

supplement, 5g of agarose, 25 ml of 10 X BU salt solution (0.26 M of $Na_2HPO_4 \cdot 7H_2O$

and 0.25 mM of $NaH_2PO_4 \cdot H_2O$), and 1ml of 20mg/ml X-gal solution in 225 ml water:

Clontech, Mountain View, CA) incubated at 30 °C for 5 days.

Total proteins extracted from yeast were separated on sodium dodecyl sulfate

polyacrylamide gels (7.5%), then transferred onto Immobilon-P membrane (Millipore,

Billerica, MA) using a semi-dry transfer apparatus (SEMIPHOR, Hoefer Scientific

Instruments, San Francisco, CA). Immunoblot analyses were performed with a LexA-

antibody for HopM1 or a HA-antibody for ARF-GEF proteins. For determining the

approximate sizes of proteins, PageRuler™ Prestained Protein Ladder Plus (Fermentas

International Inc, Ontario, Canada) was used.

**Growth curve assay for determining multiplication of *Pst* DC3000 and its
mutants in *Arabidopsis***

Arabidopsis plants for bacterial growth curve assay were grown in pots in growth

chambers (a 12 h dark/12 h light cycle, 100 µE, 20°C), until they were approximately 5

weeks old. The bacteria selected for growth curve assay were cultured in low-sodium

Luria-Bertany (LB) medium (10g/l Tryptone, 5g/l Yeast Extract, 5g/l NaCl) plus

appropriate antibiotics, at 30°C with shaking at 250 rpm. Bacterial liquid culture was

incubated to the mid- to late-logarithmic phase. Bacteria were collected by centrifugation

(3,000xg, room temperature, 30 minutes) and resuspended in sterile, de-ionized water with 0.03% Silwet L-77 (OSI Specialties, Friendship, WV). The bacterial inoculum was 1×10^8 colony forming units (CFUs)/ml, unless otherwise indicated. Plants were inoculated by dipping, and bacteria in leaf samples were quantified according to the protocol described in Katagiri et al. (2002).

Crossing *atmin7* knockout mutant (salk_012013) and knockout mutant of *BIG2* (salk_033446)

For constructing double knockout mutant lines of *AtMIN7* and *BIG2*, homozygous T-DNA insertion mutant of *AtMIN7* (salk_012013: Nomura et al., 2006) and that of *BIG2* (salk_033446) were grown on pots until they were flowering. The pollens from the mature stamens of salk_033446 were collected and applied to the stigmas of semi-mature flowerbuds of salk_012013. The artificially pollinated stigmas of salk_012013 were sealed with plastic wrap, and the whole plants were put into the growth chamber (under a 12 h dark/12 h light cycle, 100 μE, 20°C), until the artificially pollinated stigmas had developed into siliques. F_1 seeds were collected from mature siliques and germinated on the soil, and F_1 plants were analyzed by genomic PCR (Table 3-2). F_1 plants which had T-DNA insertion for both *AtMIN7* and *BIG2* were selected, and their F_2 seeds were collected. F_2 plants were analyzed by genomic PCR, and homozygous knockouts for *AtMIN7* and *BIG2* were selected. F_3 or F_4 plants were used for further analyses.

RESULTS

Identification of homozygous T-DNA insertion mutants for *Arabidopsis ARF-GEF* genes

To determine a possible role of *ARF-GEF* genes other than *AtMIN7* in Arabidopsis defense against the ΔCEL mutant, I attempted to identify T-DNA insertion mutants of seven *Arabidopsis ARF-GEF* genes. Based on the genomic PCR results, homozygous T-DNA insertion mutants of three genes (*BIG2*, *BIG3* and *BIG4*) were obtained (salk_033446, salk_044617, and salk_082249, respectively: Figure 3-4). These homozygous mutants did not have visible phenotypes in growth and development. Homozygous T-DNA insertion mutants of four ARF-GEF genes (*AtBIG1*, *GNOM*, *GNL1* and *GNL2*) were not isolated and only heterozygote plants were observed by genomic PCR (Wei-Ning Huang and Sheng Yang He, unpublished). Three heterozygous mutants of the four ARF-GEF genes (salk_066766 of *AtBIG1*, salk_067415 of *GNL1* and salk_103014 of *GNOM*) had shrunken seeds in their siliques and their germination rate were low (Wei-Ning Huang and Sheng Yang He, unpublished). The heterozygous T-DNA insertion mutants were not included in further analyses.

Confirmation of gene knockout in the homozygous T-DNA insertion mutants by RT-PCR

The homozygous salk lines chosen by genomic PCR were examined by RT-PCR to determine whether they were true knockouts. RT-PCR was performed with the primers which are specific for each *ARF-GEF* gene. After 25 cycles of PCR, transcript was not

RT indicates the reactions performed with a gene-specific primer and the T-DNA left border primer.

detected for salk _033446, indicating that it was a knockout mutant of *BIG2*. On the

contrary, transcript was detected in salk_044617 plant. However, the amount of transcript

was significantly less than that of Col-0. This indicates that salk_044617 is not a

knockout of *BIG3*, but the transcript level was reduced (Figure 3-5A).

Neither Col-0 nor *big4* (salk_082249) samples had detectable transcript after 25

cycles (Figure 3-5A). However, after increasing the number of the PCR cycles to 30, 40,

and 50 cycles, transcript was detected in Col-0 but not in salk_082249 (Figure 3-5B).

This result indicates that salk_082249 is a *BIG4* knockout mutant.

Determination of the multiplication of the ΔCEL mutant in the selected T-

DNA insertion mutants

The multiplication of the ΔCEL mutant in the three homozygous T-DNA insertion

mutants was examined. For comparison, the multiplication of *Pst* DC3000 (wild type;

fully virulent) and the *hrcC⁻* mutant (defective in the TTSS; nonpathogenic) were also

investigated. Besides selected salk lines, Col-0 and *atmin7* plants were included as

controls. Repeated assay results showed that none of the T-DNA insertion mutants

showed enhanced growth of ΔCEL as seen in *atmin7* plants (Figure 3-6). This result

indicates that knockout of *AtBIG2* and *AtBIG4* and knockdown of *AtBIG3* did not

increase the multiplication of the ΔCEL mutant.

Determination of the multiplication of the ΔCEL mutant in the double

knockout mutant of *AtMIN7* and *BIG2*

The C-terminus of *BIG2* (the product of At3g60860) had shown a weak
Figure 3-5. RT-PCR results of selected T-DNA insertional mutants of *AtBIG2*, *AtBIG3* and *AtBIG4*. (A) RT-PCR results of salk-033446, salk_044617, and salk_082249 after 25 cycles. (B) RT-PCR result of salk_082249 after 30, 40 and 50 cycles. PCR products from genomic DNA were detected (arrow) in addition to those from cDNA.
Figure 3-6. Multiplication of *Pst* DC3000, the ΔCEL mutant and the *hrcC⁻* mutant in Col-0, *atmin7* and *ARF-GEF* T-DNA insertion lines. Results are displayed as means of 4 leaves with standard errors.

interaction with HopM1$_{1-300}$ in the yeast two-hybrid assay (Kinya Nomura and Sheng

Yang He, unpublished). Although the T-DNA insertion mutant of *BIG2* (salk_033446)

did not show an enhanced susceptibility to the ΔCEL mutant, it is still possible that the

role oftBIG2 in defense may be partially redundant to and masked by AtMIN7. If so, a

double knockout mutant of *AtMIN7* and *AtBIG2* might support a higher level of

multiplication of the ΔCEL mutant than either *atmin7* or *atbig2* single mutant,. To test

this hypothesis, a double knockout mutant was constructed by crossing *atmin7*

(salk_012013) and *atbig2* (salk_033446). The F$_3$ and F$_4$ plants were tested by genomic

PCR and it was confirmed that they have T-DNA insertions in both genes. Line #6-3 was

selected for further analysis (Figure 3-7).

The multiplications of *Pst* DC3000, ΔCEL mutant, and *hrcC⁻* mutant in the F$_4$

plants of line #6-3 were compared (Figure 3-8). The *atmin7/big2* plants showed higher

multiplication of ΔCEL mutant than in Col-0, but it was not significantly higher than that

of *atmin7* mutant. Therefore, the double knockout of *AtMIN7* and *BIG2* did not fully

complement the ΔCEL mutation.

**Yeast two- hybrid assay of selected Arabidopsis ARF-GEF genes with
HopM1**

Nomura et al. (2006) reported that the C-terminus of AtMIN7 interacted with

HopM1$_{1-300}$, whereas the corresponding C-termini of three other ARF-GEFs, BIG2,

GNOM and BIG4, did not in the yeast two-hybrid assay. It is not known whether any of

the four remaining ARF-GEFs, BIG1, BIG3, GNL1 and GNL2, interacts with HopM1$_{1-300}$. In this study, the sequences of the ORFs of these four genes were aligned with other

Arabidopsis ARF-GEF genes by CLUSTALW (http://align.genome.jp/), and the

predicted C-terminus after the putative Sec7 domain of each gene was determined (Figure

3-2), following the previous experimental design (Nomura et al., 2006). The 3'-coding

regions of *GNL1* and *GNL2* were obtained by PCR from the genomic DNA of

Arabidopsis (Col-0 ecotype), and those of *BIG1* and *BIG3* were obtained by PCR from

the cDNA of *Arabidopsis*. The PCR products were subcloned into pB42AD-L vector and

sequenced, and the sequences were compared to those in TAIR (www.arabidopsis.org).

The sequences of PCR products for *BIG1, BIG3* and *GNL1* were confirmed to be

identical to those in the TAIR database, but the PCR product *GNL2* had mismatches,

resulting in two amino acid changes (Appendix 3-8). However, these two changed amino

acids were found in two independent sets of PCR, and were therefore not likely to be

mutations introduced during PCR procedures.

The PCR products were cloned into pB42AD-L vector and the recombinant plasmids

were introduced into yeasts. Previously characterized ARF-GEF clones (BIG2, BIG4,

AtMIN7 and GNOM: Nomura et al., 2006) were included in yeast two-hybrid assay with

$HopM1_{1-300}$. Among the four newly made ARF-GEF clones, BIG1, BIG3 and GNL1

were not expressed in yeast, and only GNL2 clone was expressed (Figure 3-9B). GNL2

did not show interaction with $HopM1_{1-300}$ (Figure 3-9A). In these experiments, BIG2

clone which had previously been demonstrated to have a weak interaction with $HopM1_{1-300}$

(Kinya Nomura and Sheng Yang He, unpublished) also did not interact with $HopM1_{1-300}$ (Figure 3-9A).

DISCUSSION

In this chapter *Arabidopsis ARF-GEF* genes were studied to determine whether they have roles in the defense against the ΔCEL mutant and whether their products interact with HopM1.

To determine the roles of the *ARF-GEF* genes in *Arabidopsis* defense against the ΔCEL mutant of *Pst* DC3000, homozygous T-DNA insertion mutants of seven *ARF-GEF* genes were collected. Homozygous T-DNA insertion mutants of three *ARF-GEF* genes (*BIG2*, *BIG3* and *BIG4*) were confirmed by PCR. RT-PCR results showed that the homozygous T-DNA insertion mutants of *BIG2* (salk_033446) and *BIG4* (salk_082249) were knockout mutants and that the T-DNA insertion mutant of *BIG3* (salk_044617) had a reduction in transcript level. However, salk_044617 was included in further experiments because it was the only available salk line for *BIG3* (TAIR, www.arabidopsis.org). The RT-PCR result of salk_082249 needed more PCR cycles than those of the two other salk lines (25 cycles), indicating that the transcription level of the *BIG4* is low. It is consistent with the information available from the Bio-Array Resource for *Arabidopsis* Functional Genomics. The expression of *BIG4* is very low in vegetative organs but high in anthers (the information of the expression of each *ARF-GEF* gene in different tissue is in theAppendix 3-9: Winter et al., 2007; http://www.bar.utoronto.ca /efp/cgi-bin/efpWeb.cgi).

The multiplication of the ΔCEL mutant was quantified in the selected T-DNA insertion mutants, and compared to those in Col-0 and in *atmin7* plants. In addition to the ΔCEL mutant (a mutant with an intact TTSS, but a partially deleted CEL), *Pst* DC3000 (a

wild type pathogen with an intact TTSS) and the *hrcC⁻* mutant (a mutant without a functional TTSS) were also tested. The multiplication of the ΔCEL mutant in the T-DNA insertion mutants was similar to that seen in Col-0, and none of the mutants showed increased multiplication of the ΔCEL mutant equivalent to the multiplication in *atmin7* plants. These data show that the mutation of *BIG2* and *BIG4* do not result in enhanced multiplication of the ΔCEL mutant, and that these *ARF-GEF* genes do not have a role in *Arabidopsis* defense against the ΔCEL mutant.

A prior yeast two-hybrid assay showed a weak interaction between BIG2 and HopM1$_{1-300}$, suggesting that *BIG2* may contribute to *Arabidopsis* defense against the ΔCEL mutant (Kinya Nomura and Sheng Yang He, unpublished). The double knockout mutant of *AtMIN7* and *BIG2* may therefore support increased multiplication level of the ΔCEL mutant above that shown in *atmin7*. However, the multiplication of the ΔCEL mutant in the double knockout mutant was not significantly different than that in *atmin7* mutant. In addition, the yeast two-hybrid interaction between BIG2 and HopM1$_{1-300}$ was not reproduced. Based on these data, it can be interpreted that *BIG2* does not significantly contribute to *Arabidopsis* defense against the ΔCEL mutant and it is not a host target of HopM1.

BIG4 is not likely to contribute to *Arabidopsis* defense against the ΔCEL mutant based on the ΔCEL mutant multiplication level in the T-DNA insertion mutant (salk_082249). BIG4 also did not interact with HopM1$_{1-300}$ in the yeast two-hybrid assay (Nomura et al., 2006), indicating that it is not a host target of HopM1. From its anther-specific expression (Appendix 3-9 [Winter et al., 2007]), *AtBIG4* may have roles in organ development rather than in defense.

The role of *BIG3* in *Arabidopsis* defense against the ΔCEL mutant remains unclear. The T-DNA insertion mutant of *BIG3* (salk_044617) was not a complete knockout mutant. It did not support the multiplication of the ΔCEL mutant, and this may be due to the presence of residual *BIG3* transcript. The yeast two-hybrid assay between BIG3 and HopM1$_{1-300}$ could not be performed, because the C-terminus of BIG3 was not expressed in yeast for unknown reasons.

Homozygous T-DNA insertion mutants for *BIG1*, *GNOM*, *GNL1* and *GNL2* were not isolated although heterozygous mutant plants were obtained (Wei-Ning Huang and Sheng Yang He, unpublished). These heterozygous mutants were not further analyzed. The heterozygous mutants of *BIG1, GNOM and GNL1* had abnormal seed development in the siliques (Wei-Ning Huang and Sheng Yang He, unpublished), suggesting that these *ARF-GEF* genes may function in seed or embryo development. Indeed, *GNOM* functions in embryo development, and its heterozygous mutant produces embryo-lethal seeds (Mayer et al., 1993; Vielle-Calzada et al., 2000).

The C-termini of BIG1, GNOM, GNL1 and GNL2 were tested by yeast two-hybrid assay to determine whether they interact with HopM1$_{1-300}$. GNL2 was successfully expressed in yeast, but it did not interact with HopM1$_{1-300}$ suggesting that GNL2 is not likely to be targeted by HopM1. However, the C-termini of three of the ARF-GEFs, BIG1, GNOM, GNL1, were not expressed in yeast. This could be due to the toxicity generated by those C-termini to the yeast or structural defects in the truncated ARF-GEF proteins. As a result, the interaction between AtBIG1, GNOM or GNL1 with HopM1$_{1-300}$ could not be tested in the yeast two-hybrid assay.

In this chapter it was confirmed that *AtBIG2* and *AtBIG4* do not have a significant

influence in *Arabidopsis* defense against the ΔCEL mutant. It was also demonstrated that

GNL2 does not interact with HopM1$_{1-300}$. The role of *GNL2* in defense against the ΔCEL

mutant was not determined. However, thus far, we have been unable to demonstrate that

any ARF-GEFs other than *AtMIN7* function in the defense against the ΔCEL mutant or

that they are targeted by HopM1. However, it still cannot be concluded that AtMIN7 is

the only ARF GEF that is important for *Arabidopsis* defense and the only ARF-GEF

target of HopM1.

CHAPTER 4

In vivo Subcellular Localization Imaging of Several *Arabidopsis* Proteins

That Are Putative Cargoes of Defense-Associated Cellular Trafficking

ABSTRACT

Confocal microscopy has been used for the visualization of plant-pathogen interactions in living plant cells and enabled the understanding of the characteristics of defense-associated proteins in the context of the cellular processes. In this chapter, three known or predicted extracellular *Arabidopsis* proteins (PR1, a putative lipid transfer protein (LTP) encoded by At2g10940 and FLA9, a putative arabinogalactan protein (AGP) encoded by At1g03870) were fused with GFP, and they were examined in *Arabidopsis* by western blot analyses and confocal microscopy. The immunoblot analysis results of PR1-GFP and At2g10940-GFP did not show any sign of degradation or modification of fusion proteins. The FLA9-GFP fusion was not expressed in *Arabidopsis*. PR1-GFP was localized in the intercellular space both in Col-0 and *atmin7* backgrounds. At2g10940-GFP was localized in the intercellular space in Col-0 background, but in *atmin7* background, unidentified round intracellular structures were observed. These results suggest that the localization of At2g10940-GFP may be dependent on AtMIN7-mediated vesicle trafficking pathway(s), whereas the localization of PR1-GFP is not.

INTRODUCTION

Microscopic visualization of the components of pathogens or plants during infection has been one of the most powerful experimental approaches in the study of plant-pathogen interactions. In recent years, confocal microscopic analyses of cellular proteins fused to fluorescence proteins (such as GFP and its derivatives) have revolutionized the field of plant cell biology, in large part because confocal microscopy enables monitoring the localization and dynamic changes of GFP fusion proteins in living cells or organisms (Brandizzi et al., 2004).

The interactions between *Arabidopsis* and its pathogens have been also studied by confocal microscopy. For instance, pathogens such as *Pst* DC3000 or cauliflower mosaic virus (CaMV) were tagged with GFP and used for the microscopic detection of their behaviors during infection (Badel et al., 2002; Love et al., 2007). Also, numerous defense-associated proteins of *Arabidopsis* have been studied by confocal microscopy for determining their localization in the cell.

Several known defense-associated proteins in *Arabidopsis* are components of the cellular trafficking system. PEN1 (SYP121), a protein having a role for the defense against fungal pathogens, is a SNARE protein which acts in vesicle targeting and fusion (Collins et al., 2003; Assaad et al., 2004; Mayer et al., 2009). SYP122, the closest homologue of PEN1, is also involved in the regulation of defense-associated signaling pathways (Assaad et al., 2004; Zhang et al., 2007). AtMIN7 plays a role in the defense against the ΔCEL mutant of *Pst* DC3000, and it is a putative ARF-GEF which activates ARF protein required for vesicle formation and budding (Nomura et al., 2006). Another

126

Arabidopsis protein, RabE1.d, which physically interacts with the type III secretion system (TTSS) effector AvrPto, is a small GTPase functioning in vesicle targeting. The constitutively active form of RabE1.d enhances the resistance against *Pst* DC3000 (Speth et al., 2009). All of these proteins were studied by confocal microscopy and their subcellular localizations were determined: PEN1 and SYP122 are localized in the plasma membrane (Collins et al., 2003; Assaad et al., 2004), AtMIN7 is localized in the trans-Golgi network (Tanaka et al., 2009) and RabE1.d is localized in the Golgi and plasma membrane (Speth et al., 2009). In addition to *Arabidopsis*, NbSYP132, a SNARE protein in *N.benthamiana* has role in defense (Kalde et al., 2007).

Accumulating evidence suggests that *Pst* DC3000 affects the components of defense-associated cellular trafficking pathways of *Arabidopsis* via its TTSS effectors. For instance, AtMIN7 and RabE1.d are targeted by HopM1 and AvrPto, respectively. AtMIN7 is degraded by HopM1, and the localization of RabE1.d is changed in transgenic *Arabidopsis* expressing AvrPto (Nomura et al., 2006; Speth et al., 2009; Elena Bray Speth and Sheng Yang He, unpublished). Furthermore, global gene expression analysis of *Arabidopsis* upon infection of *Pst* DC3000 showed that there was a biased suppression of genes encoding putatively secreted proteins in a TTSS-dependent manner (Hauck et al., 2003: Thilmony et al., 2006). The TTSS-dependent effect on the host vesicle traffic is also observed in other bacterial pathogens. For example, a TTSS effector of *Xanthomonas campestris*, XopJ, when expressed in tobacco, interfered with the secretion of GFP which was introduced in tobacco (Bartetzko et al., 2009).

Despite these intriguing observations, it is still poorly understood how the bacterial TTSS effector system alters the dynamic and spatial patterns of host vesicle

traffic during infection. In the case of AtMIN7, currently neither the cargoes nor the functional components of AtMIN7-dependent vesicle trafficking pathway have been elucidated. The only clue for understanding the characteristics of AtMIN7-mediated vesicle trafficking is that the *atmin7* plant has reduced and altered callose deposition in cell wall-associated PTI (Nomura et al., 2006).

In this chapter, the localization of three known or predicted extracellular *Arabidopsis* proteins were studied by confocal microscopy: PR1 encoded by At2g14610 (Laird et al., 2004), a putative protease inhibitor/seed storage/lipid transfer protein (LTP) family protein encoded by At2g10940 (Hauck et al., 2003), and a putative fasciclin-like arabinogalactan 9 protein (FLA9) encoded by At1g03870 (Hauck et al., 2003; Johnson et al., 2003). *PR1* is a representative gene which is induced in plant defense and has been extensively used as a marker for the establishment of local and systemic plant resistance. *PR1* is induced in both incompatible and compatible *Arabidopsis-P.syringae* interactions (Uknes et al., 1992; Laird et al., 2004) and by SA or SA analogues such as 2,6-dichloroisonicotinic acid (INA) or a benzothiadazole derivative (BTH) (Uknes et al., 1992; Lawton et al., 1996). PR1 is localized in the intercellular space of *Arabidopsis* based on the analysis of apoplastic fluid (Uknes et al., 1992), but its localization has not been studied by confocal microscopy. The functions of PR1 in plant resistance against bacterial pathogens are not known despite its known contributions to the resistance against fungi or oomycetes (Alexander et al., 1993; Niderman et al., 1995).

At2g10940 (a putative protease inhibitor/seed storage/lipid transfer protein (LTP) family protein) and At1g03870 (a putative fasciclin-like arabinogalactan 9 protein (FLA9) were also selected in this study. The expression of both of them was suppressed

in a TTSS-dependent manner (Hauck et al., 2003; Roger Thilmony and Sheng Yang He, unpublished), in contrast to the expression of *PR1*, which was induced in a TTSS-dependent manner. The products of these genes were suggested as putative cargoes of a defense-associated secretion pathway or a defense-associated cell wall component in *Arabidopsis* (Hauck et al., 2003): it was suggested that the TTSS-dependent suppression the two genes is the reflection of the effect to the secretion of the gene products by TTSS effectors.

These proteins were fused with GFP, and the GFP fusions were introduced into *Arabidopsis*. Their expression and localization were studied by immunoblot analysis and confocal microscopy, and their localization in Col-0 and the *atmin7* plants was compared.

MATERIALS AND METHODS

Construction of GFP fusions and their subcloning into plant expression vector

The predicted amino acid sequences of *PR1*, At2g10940 and *FLA9* were examined using the SignalP 3.0 software (http://www.cbs.dtu.dk/services/SignalP/) (Bendtsen et al., 2004; Nielsen et al., 1997) to identify putative signal sequences at their N-termini. Based on these analyses, fusions were designed to have GFP attached at the C-termini of the proteins (Figure 4-1, Appendix 4-1 to 4-3).

The ORF of *PR1* was amplified by PCR using a *PR1* clone in pBluescript II KS (+) (He laboratory culture collection #742) as the template. The ORFs of At2g10940 and *FLA9* were amplified by PCR using genomic DNA of Col-0 as a template. TaKaRa LA Taq (TaKaRa BioInc, Japan) was used for PCR. The primers used for PCR are in table 4-1. The PCR products were cloned into pCR$^{®}$2.1-TOPO (Invitrogen, Carlsbad, CA), and their sequences were determined. The ORFs were transferred to pBluescript II KS (+) containing a *sGFP* ORF (Chiu et al., 1996), in which the *sGFP* ORF is followed by the NOS terminator. In all cases, the 3' end of the ORF was attached to the 5' end of the *sGFP* ORF. Mutation-free *PR1-GFP*, At2g10940-*GFP* and *FLA9-GFP* fusions (including the NOS terminator) were subcloned into the *Xho*I/*Spe*I sites of the pBD vector (a gift From Dr. Jeff Dangl laboratory, University of North Carolina, Chapel Hill, NC), a binary vector carrying a kanamycin resistance gene for selection in bacteria, a resistance gene for herbicide BASTA (glufosinate), and a rat glucocorticoid hormone dexamethasone (DEX [Aoyama and Chua, 1997])-inducible promoter.

Transformation of recombinant plasmids into *Agrobacterium*

The pBD derivatives containing fusion ORFs were transformed into *E.coli* strain DH5α, and kanamycin-resistant colonies were obtained on solid Luria-Bertani (LB) medium supplemented with kanamycin (50 mg/ml). These recombinant plasmids were then introduced into *Agrobacterium* strain C58C1 (resistant to rifampicin and tetracycline) by tri-parental mating with the *E.coli* helper strain pRK2013.

Production of transgenic *Arabidopsis* lines expressing GFP fusions

PR1-GFP, At2g10940-*GFP* and *FLA9-GFP* gene fusions cloned in pBD vector and transformed in *Agrobacterium* were transformed into *Arabidopsis*. pBD-*PR1-GFP* and pBD-At2g10940-*GFP* were introduced into both Col-0 and the *atmin7* knockout plant, and *FLA9-GFP* gene fusion was introduced into Col-0 only. The transformation was performed following the protocol of floral dipping (Clough and Bent, 1998). Ten to fourteen-day-old T_1 plants were sprayed with 0.2 % BASTA solution (glufosinate-ammonium, trade name Finale, AgroEvo Environmental Health, Montvale, NJ) to select putative T_1 transformants. The leaf samples of BASTA-resistant T_1 plants were dipped in 30 μM DEX solution and they were examined by confocal microscopy. T_1 plants showing GFP fluorescence, an indication of GFP fusion expression, were chosen for further analysis. Plants of T_2 or later generations in each transgenic line were used for confocal microscopy and western blot analyses.

Confocal microscopy

Leaf samples were prepared from stable transgenic *Arabidopsis* plants. Prior to

confocal microscopic observation the leaf samples were dipped into DEX solution (30μM, 24 hours), to induce the expression of GFP fusions. Leaf pieces were cut and mounted in water, followed by imaging with LSM510 META inverted confocal laser scanning microscope (Zeiss). A 40x oil immersion objective was used.

The GFP fusions were excited at 488 nm from an argon laser, and the emission light was filtered with a 505-530 nm band-pass filter to acquire the GFP signal. The autofluorescence from chloroplasts of mesophyll cells was filtered by a 615 nm long-pass filter. All images were examined and processed with Carl Zeiss AIM Version 3.2. Some images were adjusted using Adobe Photoshop Element version 5.5 or 7.0 in brightness and contrasts.

Plasmolysis of leaf samples

Leaf samples were dipped in 1M Tris-HCl solution (pH 7.5) for up to 30 minutes prior to confocal microscopic observation. The samples were mounted on slides in Tris-HCl solution (pH 7.5) or water.

Protein extraction and western blot analyses

Total protein samples were extracted from transgenic *Arabidopsis* plants expressing GFP fusions. A leaf from each transgenic plant was detached and dipped in the DEX solution (30 μM). After 24 hours, 20 mg of each leaf sample (fresh weight) was ground in 200 μL of the 2X SDS buffer [100 mM Tris-HCl pH 6.8, 200 mM DTT, 4% SDS, 20% glycerol]. Extracts were immediately heated at 90°C for 10 minutes and then frozen at -20°C.

Prior to the loading of each protein sample on protein gels, extracts were thawed at room temperature, heated at 90°C for 3 minutes, and centrifuged at $10,000 \times g$ for 1 minute. Ten to 20 μL of the supernatant of each sample was used for SDS-PAGE electrophoresis (the volumes of different samples were the same in an immunoblot analysis). Total proteins were separated on precast gradient gels (4-20%, ISC BioExpress, Kaysville, UT) or hand-made SDS-PAGE gels (7.5, 10, or 12% gels), then transferred to Immobilon-P membrane (Millipore, Billerica, MA) using a semi-dry transfer apparatus (SEMIPHOR, Hoefer Scientific Instruments, San Francisco, CA). Immunoblot analyses were performed with a GFP-specific antibody (Santa Cruz Biotechnology, Inc., Santa Cruz, CA). For estimating the sizes of proteins, PageRuler™ Prestained Protein Ladder Plus (#SM1811, Fermentas International Inc, Ontario, Canada) was used.

RESULTS

Production of transgenic *Arabidopsis* expressing GFP fusion proteins

The ORF of *sGFP* (Chiu et al., 1996) was attached to the 3' ends of the selected

Arabidopsis genes (Figure 4-1). These fusion ORFs were introduced into *Arabidopsis*,

and BASTA-resistant T_1 plants were selected. More than 10 different T_1 plants

transformed with pBD-*PR1-GFP* or pBD-At2g10940-*GFP*, respectively, survived after

BASTA spray. T_1 plants showing the GFP-fluorescence were collected. From these plants,

two independent PR1-GFP or At2g10940-GFP lines were selected for further

experiments (Table 4-2, Table 4-3 and Appendix 4-4 and 4-5). On the other hand,

fluorescence was not detected in any of BASTA-resistant T_1 plants transformed with

pBD-*FLA9-GFP*. pBD-*PR1-GFP* and pBD-At2g10940-*GFP* were transformed into the

atmin7 mutant as well. Among the BASTA-resistant T_1 plants transformed with *PR1-*

GFP or *At2g10940-GFP*, two independent PR1-GFP or At2g10940-GFP lines showing

GFP fluorescence were selected for further experiments (Table 4-2, Table 4-3 and

Appendix 4-4 and 4-5).

The transgenic *Arabidopsis* expressing PR1-GFP or At2g10940-GFP were

analyzed by western blot analysis. The western blot analysis results showed that the

protein bands of the expected sizes for both PR1-GFP (approximately 44 kDa) and

At2g10940-GFP (approximately 58 kDa) fusion proteins were detected in both Col-0 and

in the *atmin7* mutant backgrounds using the GFP-specific antibody (Figure 4-2). Besides

the protein bands corresponding to PR1-GFP protein and At2g10940-GFP fusion proteins,

there were additional bands corresponding to the size of GFP. The intensity of the GFP-

sized bands was variable in different leaf samples (Figure 4-2). The transgenic

Arabidopsis plants which were transformed with the FLA9-GFP plasmid did not shown

any GFP-specific bands in western blot analysis.

The subcellular localization of PR1-GFP in *Arabidopsis*

Confocal microscopic examination showed that PR1-GFP was located along the

cell edge in the Col-0 genetic background (Figure 4-3A and B) in independent transgenic

lines. To determine whether the cell-edge fluorescence represents localization of PR1-

GFP fusion at the plasma membrane or in the intercellular space between cells, I

performed plasmolysis to separate the plasma membrane from the cell edge. Under this

condition, PR1-GFP was clearly observed in the intercellular space (Figure 4-3C and D).

This intercellular localization of PR1-GFP is consistent with its localization based on the

intercellular wash fluid analysis, as previously reported (Uknes et al., 1992). Besides the

intercellular space, PR1-GFP was also shown along the putative *Arabidopsis* cell wall.

Almost all epidermal cells after plasmolysis showed localization of PR1-GFP in the

intercellular space including the putative cell wall (Figure 4-3C). The examination of

mesophyll cells showed a similar localization pattern (Figure 4-3D), but the intensity of

fluorescence from the intercellular space was often lower than that along the putative cell

wall.

The localization of PR1-GFP was also examined in transgenic lines with the

atmin7 background. PR1-GFP was found along the cell edge, like that in the Col-0

background (Figure 4-4A and B). After plasmolysis PR1-GFP was found in the

intercellular space and the putative cell wall as shown in epidermal cells and mesophyll
Figure 4-3. Localization and expression of PR1-GFP in *Arabidopsis*, line #1 (Col-0). (A) and (C): Localization of PR1-GFP in epidermal cell layer before and after plasmolysis, respectively. cells of the Col-0 background (Figure 4-4C and D). Again, the intensity of fluorescence from the intercellular space was often lower than that along the putative cell wall. Thus, the localization of PR1-GFP inCol-0 and *atmin7* knockout background did not appear to be different.

The subcellular localization of At2g10940-GFP in *Arabidopsis*

The localization of At2g10940-GFP fusion protein in independent transgenic *Arabidopsis* lines was examined by confocal microscopy. At2g10940-GFP was found along the cell edge (Figure 4-5A and B), which was similar to the localization of PR1-GFP. After plasmolysis At2g10940-GFP was detected in the intercellular space and along the putative cell wall (Figure 4-5C and D). In mesophyll cells, the intensity of fluorescence of At2g10940 from the intercellular space was often lower than that along the putative cell wall.

Next, the localization of At2g10940-GFP in the *atmin7* background was examined in independent lines. Compared to that in Col-0 background, the At2g10940-GFP was found in not only along the cell edge, but also in the unidentified, round structures (Figure 4-6). This localization pattern was shown in two independent lines (Appendix 4-4 and 4-5).
Figure 4-5. Localization of At2g10940-GFP in *Arabidopsis*, line #9 (in Col-0 background). DISCUSSION

In this chapter, as part of an effort to establish a GFP fusion-based, *in planta* imaging system for long-term study of the dynamic effects of pathogen infection on vesicle trafficking and/or protein secretion in *Arabidopsis*, the subcellular locations of GFP fusions of two *Arabidopsis* extracellular proteins were examined by confocal microscopy and stable transgenic plants expressing these proteins were produced. These proteins were selected based primarily on the hypothesis that they might be related to extracellular defense or putative cargoes of defense-associated secretion pathways.

Numerous studies have shown that PR1 is an extracellular protein associated with various forms of plant disease resistance, although transgenic *Arabidopsis* plants stabling expressing a PR1-GFP fusion has not yet been reported. Although direct evidence for an association of At2g10940 and At1g03870 to plant defense is lacking, the products of these genes, a putative protease inhibitor/seed storage/lipid transfer protein (LTP) family protein and a putative fasciclin-like arabinogalactan 9 protein (FLA9), respectively, were suggested as putative cargoes of a defense-associated secretion pathway or a defense-associated cell wall component in *Arabidopsis*.

Both PR1-GFP and At2g10940-GFP were detected by western blot analysis in transgenic plants. The detected bands were of expected sizes, without significant degradation. This result indicates that both GFP fusion proteins were successfully expressed in the transgenic *Arabidopsis*, and the GFP fluorescence detected by the confocal microscopy reflected fusion proteins. There were additional bands corresponding to the approximate size of GFP in several protein samples, but the

intensity of the GFP-sized bands was variable in different leaf samples. There was no correlation between a specific transgenic line and the presence or intensity of the GFP-sized band, suggesting that appearance of such bands is likely caused by sample preparation. Consistent with this possibility, these bands were not detected in every examined sample. I examined the images acquired by confocal microscopy to see whether there is fluorescence in the cytoplasm, in which GFP alone is known to reside (Appendix 2-2), but there was no significant fluorescence detected in the cytoplasm.

The results from confocal microscopic analyses coupled with plasmolysis showed that both PR1-GFP and the At2g10940-GFP were localized in the intercellular space of *Arabidopsis* (Col-0). Such localization is consistent with their predicted localization based on the presence of a putative N-terminal signal sequence, and, in the case of PR1-GFP, to that based on the apoplastic fluid analysis (Uknes et al., 1992). The plasmolysis condition which was applied to the leaves expressing PR1-GFP and At2g10940-GFP was the same as that applied to the leaves expressing the PIPA2-GFP fusion, which is known to be localized in the *Arabidopsis* plasma membrane (EGAD line Q8: Cutler et al, 2000). It was previously shown that after plasmolysis PIP2A-GFP remains in the plasma membrane (Speth et al., 2009), which looked clearly different from PR1-GFP or At2g10940-GFP fusions found primarily in the intercellular space after plasmolysis.

I noticed that after plasmolysis, both PR1-GFP and At2g10940-GFP were found not only in intercellular space but also in the putative cell wall. This result suggests that PR1 and the LTP encoded by At2g1940 may have interaction with the cell wall. Further experiments may be performed with plasmolysis plus cell wall-specific marker or detector, such as propidium iodide, which stains the plant cell wall (Chen et al., 2009). It

146

is possible that the putative cell wall localization is caused by transgenic overexpression of GFP fusions. If so, future experiments should be performed to reduce the expression of fusion proteins by reducing DEX concentration or induction time.

The localization of PR1-GFP and At2g10940-GFP was also determined in the *atmin7* knockout mutant. PR1-GFP was shown in the intercellular space and along the putative cell wall, similar to its localization in Col-0. This result is supported by the observation that PR1 in the *atmin7* plants was detected in the intercellular wash fluid sample of those transgenic plants by the immunoblot analysis (Kinya Nomura and Sheng Yang He, unpublished). Together these results indicate that either PR1 is not delivered to the intercellular space and/or the cell wall via the AtMIN7-mediated vesicle trafficking pathway, or PR1 could be transported by multiple vesicle trafficking pathways including that mediated by AtMIN7.

In contrast, the At2g10940-GFP fusion protein expressed in the *atmin7* mutant showed interesting dual localization: multiple, round structures were found inside the cells, besides the localization along the cell edge. It is unlikely that those round structures were from the nonspecific aggregation or degradation of At2g10940-GFP, considering that the western blot analysis result revealed a protein with the expected size. It is also not likely that those round structures were from an aggregation of the putative GFP, which was detected in western blot analysis, because the fluorescence from the GFP alone does not show such distinct localization pattern (Appendix 2-2). Also, there was no significant fluorescence in the cytoplasm, in which GFP is known to reside (Appendix 2-2). The possibility that the overexpression of At2g10940-GFP caused the appearance of nonspecific structures can also be excluded, considering that the *Arabidopsis* plants

expressing PR1-GFP and At2g10940-GFP expressed in the Col-0 genetic background and the plants expressing PR1-GFP in the *atmin7* background did not show these intracellular structures. In addition, the round intracellular structures were shown in two independent transgenic lines in the *atmin7* mutant background (Appendix 4-5). Altogether, these results raise the possibility that the *atmin7* mutation affected secretion of the At2g10940-GFP, and, as a result, at least some At2g10940-GFP was retained in the cytoplasm.

Several further experiments need to be performed to confirm my localization study of At2g10940-GFP. Specifically, plasmolysis of the transgenic *atmin7* plant expressing At2g10940-GFP is needed. Some At2g10940-GFP was detected along the cell edge, but its exact localization was not determined. Without plasmolysis, it is difficult to distinguish the intercellular space from the plasma membrane or even the cytoplasm. If the cell-edge localization of At2g10940-GFP in *atmin7* plants represents the intercellular space, the result can be interpreted that the secretion of the At2g10940-GFP fusion protein was blocked only partially in the *atmin7* mutant and suggests existence of multiple pathways for the secretion of At2g10940-GFP. On the other hand, if the cell-edge localization of At2g10940-GFP represents the plasma membrane or the cytoplasm, the result would suggest a more significant block of At2g10940-GFP secretion in the *atmin7* background. The identity of the At2g10940-GFP-associated round structures is unknown and remains to be elucidated. They could represent nonspecific aggregations of At2g10940-GFP or can be some type of subcellular structures.

The fusion protein FLA9-GFP was not observed by confocal microscopy in any of the BASTA-resistant plants. Western blot analysis also did not show any specific band

detectable by GFP antibody. These results suggest that the expression of FLA9-GFP in T_1

plants was not successful. FLA9 is a member of fasciclin-like arabinogalactan protein

(FLA) family of *Arabidopsis* (Johnson et al., 2003). FLA proteins possess a C-terminal

hydrophobic domain, which is cleaved and replaced by a glycosylphosphatidyl inositol

(GPI) anchor (Gaspar et al., 2001). Therefore, it is possible that the C-terminal GFP in

FLA9-GFP was cleaved off, and as a result, FLA9-GFP fusion protein was not correctly

expressed.

CHAPTER 5

Conclusions and Future Perspectives

In the pathogenic interactions between *Arabidopsis* and *Pst* DC3000, one important question related to TTSS effector-associated virulence is how *Pst* DC3000 TTSS effector proteins affect cellular processes in the host plant. The recent study of HopM1, a TTSS effector of Pst DC3000, and AtMIN7, its host target and a putative ARF-GEF protein in *Arabidopsis*, supported the idea that one of the functions of TTSS effectors is to contribute to the virulence of *Pst* DC3000 by suppressing the vesicle trafficking in plant cells. This led to the research direction that combined the study of plant-pathogen interactions with a cell biological approach. In my dissertation the localization of HopM1 in plant cells was studied by confocal microscopy in order to understand how its action in host cells contributes to the virulence of *Pst* DC3000. I also attempted to determine the specificity of the defense-associated role of *AtMIN7* compared with that of other *ARF-GEF* gene family members. Finally, the localization of several putative cargo proteins of defense-associated protein secretion pathways were compared in Col-0 and the *atmin7* backgrounds.

The results in the localization study of HopM1 show that hopM1 is localized in TGN and early endosome. The N-terminus of HopM1 (HopM1$_{1-300}$) is also localized in the TGN and early endosome like the full-length HopM1, although it seems more transient compared to that of full-length HopM1. With the previous study showing that HopM1 interacts and destabilizes AtMIN7 (Nomura et al., 2006), this is another important clue for understanding the virulence-associated function of HopM1. A possible further research direction could be the study of HopM1 fusion proteins in *Arabidopsis*. After collecting transgenic *Arabidopsis* lines expressing all needed HopM1 fusion proteins and confirming the correct expression of the fusion proteins, I suggest the

following experiments. First of all, confocal microscopic examination of expression of HopM1 fusions over time is essential. Microscopic observation at early and later time points (within or after 5 hours post-DEX treatment) could be performed. It is also necessary to determine whether tissue death of transgenic *Arabidopsis* plants is induced by full-length HopM1 fusion proteins in a similar way as described for the full-length HopM1 without fluorescence protein tag (Debroy et al., 2004; Nomura et al., 2006).

Nomura et al (2006) showed that the multiplication of the ΔCEL mutant is enhanced in transgenic *Arabidopsis* expressing HopM1. They also showed that the first 300 amino acids of HopM1 expressed in *Arabidopsis* suppressed the multiplication of the ΔCEL mutant complemented with *hopM1* and *shcM* ORFs. These results could be reconfirmed in the transgenic *Arabidopsis* expressing full-length or truncated HopM1 fusion proteins. Compared to previous research results with HopM1 without fluorescence tag, it is possible to detect the localization change of HopM1 fusion proteins by confocal microscopy with time courses. Related to this, it would be interesting to determine the localization of HopM1 fusion proteins after the infiltration of the ΔCEL mutant complemented with *avrE* and its chaperone ORFs, considering that AvrE and HopM1 are both from the CEL of *Pst* DC3000 and are functionally redundant (Alfano et al., 2000; DebRoy et al., 2004).

HopM1 suppresses the SA-dependent callose deposition in the *Arabidopsis* cell wall (DebRoy et al., 2004), but the mechanism of this suppression was not determined in previous studies. With fluorescence protein-tagged HopM1, it is possible to detect the localization change of HopM1 (full-length or truncated) associated with this suppression: the GFP/YFP fusions of HopM1 can be compared before and after the application of SA

or its analogue, BTH. Also, considering that flg22 induces callose deposition in

Arabidopsis (Gomez-Gomez et al., 1999; Underwood et al., 2007) and that

PAMP/MAMP-triggered signaling pathway in *Arabidopsis* has positive interplay with

SA-mediated signaling (Tsuda et al., 2008), it would be interesting to detect the

localization of HopM1 fusion proteins upon the treatment of flg22. In addition, it would

be also interesting to detect the potential change of specific marker proteins of endosomal

compartments, including AtMIN7, after the infiltration of bacterial pathogens or in

transgenic *Arabidopsis* expressing HopM1 or its fusion proteins.

The experimental design for determining the localization of HopM1 in plant cells

is not a natural situation. It depends on the *in planta* overexpression of a specific TTSS

effector (or its fusions) and the amount of the effector protein is unnaturally high

compared to that translocated by the TTSS. The ideal approach is to introduce HopM1

fusions in *Pst* DC3000 and let it be delivered through the TTSS, but this approach was

not successful in previous studies. In this study, instead, the timing of microscopic

observation was limited, to avoid the overexpression of HopM1 fusion proteins as much

as possible.

The results of the study of *Arabidopsis ARF-GEF* genes in this dissertation are

not sufficient to obtain a clear determination of the role and importance of each *ARF-*

GEF gene in defense. None of the studied *ARF-GEF* genes, however, showed the

characteristics indicating that they are involved in *Arabidopsis* defense against the ΔCEL

mutant. The possibility that *AtBIG2* has additive role in the defense against the ΔCEL

mutant was not supported, based on the results from the multiplication of the ΔCEL

mutant in the T-DNA insertional mutant and the yeast two-hybrid assay with HopM1.

From the multiplication result in the knockout mutant and from the yeast two-hybrid

assay data, respectively, we can conclude that *AtBIG4* and GNL2 are not important for

defense against the ΔCEL mutant. The studies of T-DNA insertional mutants of several

ARF-GEF genes suggest their possible roles in development and growth of *Arabidopsis*

(Steinmann et al., 1999; Geldner et al., 2003; Teh and Moore, 2008; Richter et al., 2008;

Tanaka et al., 2009), but this was not studied in this dissertation. Although the defense-

associated functions of *Arabidopsis* ARF-GEF genes and their physical interactions with

HopM1$_{1-300}$ were not completely determined in this chapter, it is still possible that these

ARF-GEF genes are involve in the defense against other pathogens for *Arabidopsis*

which are not *Pst* DC3000, such as fungal pathogens. It would be interesting to study the

roles of these genes in defense against the non-bacterial pathogens.

The location of several *Arabidopsis* proteins which are putative cargoes of

defense-associated protein secretion was studied by confocal microscopy. In this study

the localization was determined in Col-0 and the *atmin7* backgrounds. PR1-GFP was

localized in the intercellular space, and this localization was not changed in the *atmin7*

background. On the other hand, At2g10940-GFP showed an interesting intracellular

localization in the *atmin7* background, suggesting that its location is affected by the

AtMIN7-mediated trafficking. It would be interesting to study the role of At2g10940 in

Arabidopsis defense. Unfortunately, we do not have sufficient information for

understanding the function of At2g10940 besides its expression pattern (induced by the

hrpS⁻ mutant and suppressed by *Pst* DC3000 [Hauck et al., 2003; Roger Thilmony and

Sheng Yang He, unpublished]). At2g10940 is annotated as a lipid transfer protein (LTP),

but the nucleotide sequence of At2g10940 does not share high similarity with other LTP

genes (The Arabidopsis Information Resource, http://www.arabidopsis.org). Considering

the altered papilla formation in *atmin7* mutant after the infiltration of the ΔCEL mutant

(Nomura et al., 2006) and the old annotation of At2g10940 as a putative cell wall

component (Hauck et al., 2003), At2g10940 might encode a putative component of

papillae. This idea can be tested by the infiltration of mutant bacteria which induce cell

wall-associated PTI into transgenic plants expressing Atg210940-GFP (the promoter can

be substituted by its native promoter). The study of T-DNA insertional mutant of

At2g10940 is challenging, because mutants containing T-DNA insertion in the ORF of

At2g10940 are not available (The *Arabidopsis* Information Resource,

http://www.arabidopsis.org). In the case of *FLA9,* this study does not provide data for its

localization in *Arabidopsis* cells, possibly due to its structural characteristics. There is an

example of GFP fusion design for an arabinogalactan protein (AGP), in which the GFP

was inserted after the putative N-terminal signal sequence (Sun et al., 2004), but this

approach requires an exact prediction of N-terminal signal sequence. Like At2g10940,

FLA9 is induced by *hrpS* mutant and suppressed by *Pst* DC3000 (Hauck et al., 2003), but

other characteristics of FLA9 are unknown, and there is no available mutant containing

T-DNA in its ORF (The *Arabidopsis* Information Resource, http://www.arabidopsis.org).

The experimental system used in this study, (i.e., DEX-induced production of

GFP fusions and confocal microscopy) has advantages in that GFP fusion construction

enables the visualization of the localization of selected *Arabidopsis* proteins in living

cells under different conditions. For instance, the factors affecting *Arabidopsis* defense

such as the infiltration of different bacteria or application of chemical agents such as

BTH or flg22 can be used for the localization study of GFP/YFP fusion proteins: some of

these suggested conditions were preliminarily applied to the transgenic *Arabidopsis* expressing PR1-GFP (Appendix 4-6 to 4-8). On the other hand, using a DEX-inducible promoter had advantages and limitations. It was useful to control the expression and timing of transgenes, which is advantageous compared to using a constitutive promoter. At the same time, the DEX-inducible promoter drives high expression of transgenes resulting in excessive amount of fusion proteins. This situation can make the localizations of fusion proteins incorrect by the "over-spill" of the overexpressed fusions into unrelated subcellular compartments (Crofts et al., 1999; Brandizzi et al., 2004). Also, compared to constitutive expression or native promoter-dependent expression, DEX-induction of transgenes depends on the uptake of the DEX into the plant tissue through stomata. The uptake of DEX in each experiment was not the same, so the expression level of GFP or YFP fusion proteins was not completely predictable.

Appendix 3-2. The genomic sequence of *AtBIG2* (At3g60860). Start codon (ATG) and stop codon (TGA) are in red and bold letters. Exons are in yellow color and capitals, and introns are in violet and small letters. The putative T-DNA insertion of salk_033446 is highlighted with green color. The forward and reverse primers for genomic PCR to screen homozygous salk_033446 are bold, underlined and black-colored. The forward and reverse primers for RT-PCR are in bold, underlined and blue letters.

Appendix 3-8. Comparison of the nucleotide sequences and amino acid sequences of the C-termini of GNL2. (A) The comparison of the nucleotide sequences of the C-termini of *GNL2* in TAIR (GNL1-T) and that of the clone used for yeast two-hybrid assay (GNL1-C). The different nucleotides are highlighted in yellow color. (B) The comparison of the amino acid sequences of the C-termini of GNL2 in TAIR (GNL1-T) and that of the clone used for yeast two-hybrid assay (GNL1-C). The different amino acids are highlighted in blue color.
