#### THE SHRINKAGE OF POTATOES IN STORAGE.

#### Introduction.

It is a well known fact that potatoes lose weight when kept in storage. As several investigators have discovered, this loss is due to evaporation of water and to changes caused by the process of respiration in the organic matter. Considerable amounts of potatoes are kept over winter by the potato growers for the purpose of selling them in the spring when the price is usually higher. Therefore, if cheap and convenient methods of storing the tubers can be discovered, that will lessen the amount of shrinkage, these will be the means of saving money to the grower. Even determining how much the loss in weight will be, will undoubtedly be of value to the grower in helping him to decide whether it will pay to keep the potatoes over winter or not. Briefly stated, the primary purpose of this experiment is to solve such problems as the ones mentioned.

A few experiments on this subject have been carried on by men in different parts of this country and in other countries. A brief survey of what these investigators have found would not be out of place at this time.

#### Resume of Literature.

One of the first investigators was Nobbe. He studied the changes in weight and in chemical composition as influenced by temperature, moisture, light, etc. His con-\* Landw. Vers. Stat., 7(1865) 452 -461., obs. in E.S.R.V.

3 p. 494.

clusions were: that the controlling factors in determining the loss in weight by keeping were first of all heat (temperature) and next in importance was moisture in the air. Heat increased the losses and moisture lessened them. Light had no perceptible effect on the loss in weight. The proportions of water and carbonic acid given off were four times as much of the former as of the latter. This experiment was carried on under artificial conditions and with a small number of tubers.

Muller and Thurgeau<sup>\*</sup> found that three distinct changes take place in the tubers, namely, respiration, sugar formation and retrogrades starch formation.

E. Wollny<sup>\*\*</sup> conducted an experiment on a larger scale. He took twelve different varieties and selected 100 tubers from each, early in October. These were placed in lead cylinders in a moderately dark, deep, day cellar, where the temperature varied from 6° to 11° C. The tubers were weighed the first and fifteenth of each month, beginning in October and continuing to April 1st. After that time the weight was taken the first of each month. "Under the conditions of the experiment the greatest losses in weight were directly after digging and decreased from then till the first of March, when they commenced to increase." The average percentage of losses of the twelve varieties were

as follows for each month: Oct. 202%, Nov. 1, 18%, Dec. 50%, Jan. 50%, Feb. 81%, Mar. 41%, April 50%. Wollny stated that  $0^{\circ} - 10^{\circ}$ C.  $(32^{\circ} - ,55)^{\circ}$ F) is the most rational temperature for keeping potatoes since within these limits the respiartion is low. Losses of organic matter increase in proportion to the growth of sprouts. When they start, the loss in weight is rapid.

C. O. Appleman<sup>\*</sup> after carrying on experiments at the Maryland Experiment Station, states that potatoes lose weight due to evaporated water and respired carbon dioxide. Dry conditions favor evaporation. The loss of CO<sub>2</sub> is higher at high temperatures. The greatest loss in weight occurs just after digging and decreases during the winter months. At the beginning of the period of warm weather sprouting commences and the loss in weight rapidly increases. A storage temperature of slightly above freezing is best for seed potatoes but for culinary purposes a moderately dry well ventilated cellar, temperature 38° to 42° F. is prefarable.

L. R. Taft and U. P. Hedrick, \* in 1893 stored 180 pounds of potatoes in a barrel in a potato basement and found that the tubers lost five per cent of their weight between Sept. 30, 1893 and Mar. 28, 1894. On May first they weighed them again and found an additional loss of \* Appleman, CO.O. Changes in Irish Potatoes During Stor-

age. Maryland Agr. Exp. Sta. Bul. 167. pp. 327-34. \*\* Taft, L. R. and U. P. Hedrick. Does it Fay to Keep Potatoes Over Winter. Mich. Agr. Exp. Sta. Bul. No. 119. p. 9.

 $6\frac{1}{2}$  per cent making a total of  $11\frac{1}{2}$  per cent loss between September 30th and May 1st. At the latter weighing the tubers were beginning to get soft and flabby. They state also that the basement was perhaps a little warmer than it should have been. They recommend a well ventilated roothouse, kept at about  $45^{\circ}$ F. or a little lower as a very good place for keeping potatoes.

In 1897. R. H. Price\* of the Texas Agricultural Experiment Station, tried several methods of storing potatoes. The author states that the tubers rotted rapidly there because of moisture and warm weather. Tubers were stored in sand in a barrel but they rotted soon. Also, some were placed in the ground, one foot under the surface; tiling was run thru the center to give ventilation but under these conditions the tubers were rotted in six weeks. Another plan was to spread the tuters on the ground under partial shade and cover them with hay about two inches deep. They were kept moist by sprinkling with water from a hose. About fifty per cent of them kept till the first of October. Several rows of potatoes were left in the ground and a plow was used to throw dirt upon each They were left in this condition until the 15th of row. August and 75 per cent had kept well; by the first of September fifty per cent had decayed. A few sound ones were found on the 15th of February.

F. Parisot\* states that a temperature of  $8^{\circ}$ C. is the best for storing potatoes either for food or for seed because at this temperature the respiration, combustion and formation of starch are considered as off setting the formation of sugar, and that at a higher temperature the quantity of sugar is smaller than at a lower temperature.

A storage test was made by W. Christie\*\*, at the Hedemarken County Experiment Station by placing potatoes on the soil surface and covering them with alternating layers of straw and dirt. Two piles of tubers, of the General Cronje variety were spilled 12 meters wide by three meters long and as high as the tubers would lie. The piles were covered with two layers of straw alternating with two layers of dirt. The larger pile was ventilated at the surface of the ground and at the top of the pile; the smaller one, only at the top. The storage period was between Nov. 1, 1908 and Apr. 20, 1909. Temperature readings at ten day intervals showed a minimum for the period of -23.9 C. When the piles were opened, a few potatoes in the top layer were frozen. Bacterial rot had spoiled considerable quantities, probably because of moist condition of the potatoes when stored. In the

large piles 43 per cent of the tubers were sound as compared with 54 per cent in the small piles.

Denaiffe<sup>\*</sup> states that the loss in weight of stored potatoes varies with the variety.

At the Agricultural Experiment Station in Arkansas<sup>\*\*</sup> and Indiana<sup>\*\*\*</sup> tests have been carried on to determine the keeping qualities of different varieties.

Other investigators on the loss of weight of potatoes but whose writings are not at present available to the writer are:

- R. Heinrick (Zweiter Ber. landw. Vers. Stat. Rostock 1894 p.229).
- E. J. Woodhouse and H. L. Dutt (Agr. Jour. Bihar and Orissa (India), 1, 1913. No. 2, pp. 115-137.
- Bengal Quarterly, published by Department of Agriculture, India, Jour 3(1909) No. 1. pp.1-12.

The following are the questions which the writer has tried to answer in this work:

1. How does storing potatoes in crates, in bins (in cellar), in pits in the ground, wrapped in newspaper, one and two thicknesses effect the shrinkage?

2. At what time of the storage season does the greatest shrinkage take place?

3. Does the spraying of potatoes while growing affect the shrinkage in storage?

1191 tubers or about 11 bushels of the Sir Walter Raleigh variety were brushed, weighed and diameters measured separately. Each tuber was numbered with India ink and the points where the diameter was measured were marked so that it would be taken at the same points again. Most tubers have three dimensions or diameters: length, breadth, and thickness; the one giving the breadth was measured. This was done by means of a caliper. Ordinary postal scales were used for weighing. Weighing and measuring were begun one week after the potatoes were dug and was completed two weeks after, on November 28th. On account of the limited amount of time that the writer had at his disposal the work could not be completed in a shorter time as was desired.

100 tubers (that had been sprayed) were placed in each of the following conditions; in bins, in crates, in pits in the ground and in one and two thicknesses of newspaper wrapped around each tuber. The potatoes in the pits were two feet below the surface of the ground, with enough leaves and straw over them to keep the soil from coming in direct contact with the tubers. This was put on so that they could be easily found when dug up again. The potatoes wrapped in paper were placed in boxes. This part of the experiment was repeated by putting 25 sprayed injured tubers in the same conditions. Now, the same amounts of unsprayed potatoes were placed in the same conditions. The purpose of handling injured tubers in the same way was to see if they would be effected differently.

All of the potatoes except those in the pits were kept in a moderately well ventilated potato cellar, the temperature ranging from  $40^{\circ}$  to  $50^{\circ}$ F. during the whole storage period. The atmosphere contained slightly more moisture than that outside. The weighing and measuring was done on the 28th of each month, April 28th being the last.

#### Results.

The unsprayed potatoes, wrapped in two thicknesses of newspaper did not keep well. They were attacked by a fusarium rot so that in February 6 of the 100 were starting to rot and they were thrown out of the experiment. On March 11th more had to be thrown out, making a total of 17 rotten ones in 125. The rotting, undoubtedly was

caused in part by the moisture and higher temperature kept near the tubers by two thicknesses of paper. The other potatoes kept well, even the injured ones. Those that were under ground, when dug were firm and all sound. Their increased weight was probably due to moisture absorbed from the soil.

In some instances there was a slight gain in weight over the preceding month as may be seen by referring to table I. These gains occurred mostly during the months of February and March when the losses in the others were the least. No reason for this gain can be given except that it may be due to a greater amount of moisture in the atmosphere at this time. In the case of the injured tubers, there was no appreciable difference between the percentage of shrinkage in them and the uninjured ones, for the whole length of time.

Tables III and IV contain data which answers the first question. For the month of December those tubers sotred in bins lost the most by weight, 6.76 per cent while those wrapped in one thickness of paper and those in crates showed the least loss of all stored above the ground. This holds true also for the period November 28th to April 28th. In the other months there was more variation and on that data no general rule can be laid down that will hold for each month. There is a reason why the shrinkage should take place more rapidly when potatoes are in bins than in crates, wrapped in paper.

# Table V.

Giving the differences in per cent between sprayed and unsprayed potatoes in changes of weight and diameter.

	In Bins	In Crates	l Thickness Paper	s 2 Thick Pape <b>r</b>	. In Ground	i Av.		
Unsprayed	-2.62 <del>}</del> %	-3.32%	49%	-4.33%	.14%	-1.34%

Sp <b>rayed</b>	-3.60%	-4.42%	-2.67%	-4.8%	70%	-3.24%		

When potatoes are in piles as in bins, they are kept warmer than when in small piles as in crates and when wrapped in paper. According to other investigators, Nobbe<sup>\*</sup> in particular, heat increases the losses. The shrinkage in size as measured by the diameter, in the main, follows that of the loss in weight but there are some variations between December and April.

From the averages as given in table III and IV, one can easily see that the greatest shrinkage takes place in the month just following the digging, and decreases from then till March, when it begins to increase. The chief cause for this fact is the temperature; it being lower during January and February, the chemical changes are less active and there is also less evaporation of water.

As to the question whether spraying effects the shrinkage of potatoes, one may conclude from the figures given in table V that it does. An average of the percentagees of losses and gains for unsprayed potatoes stored in the different places shows that they have lost only 1.34 per cent of their original weight while the sprayed potatoes placed under similar conditions have lost 3.66 per cent, a difference of 2.32 per cent in favor of the unsprayed. Shrinkage as measured by diameter follows the same rule though there is not so great a difference between the sprayed and unsprayed.

\* E. S. R. V.3. p.494.

--11--

Conclusions and Summary.

1. Potatoes shrink the least when placed in pits, at least two feet deep and covered with earth so that they will not freeze. The loss in weight is greatest when potatoes are put in large piles as in bins. This is due to the fact that there is a higher temperature in the piles. Ventilating the cellar and lowering the temperature, but not to freezing point, would overcome this to a large extent.

2. As was clearly brought out by the data given, potatoes shrink in storage more in the month just after being dug than at any other time; the losses are least in February.

3. Sprayed potatoes lose more weight in storage than the unsprayed.
