ABSTRACT

BEAM DYNAMICS CHARACTERIZATION AND UNCERTAINTIES IN THE MUON g-2 EXPERIMENT AT FERMILAB

By

David Alberto Tarazona

The first measurement of the positive muon magnetic anomaly, $a_{\mu} \equiv (g_{\mu} - 2)/2$, from the Fermi National Accelerator Laboratory (Fermilab) Muon g-2 Experiment (E989) yielded an experimental relative uncertainty of 0.46 ppm, which combined with the previous measurement from the Brookhaven National Laboratory (BNL) Muon g-2 Experiment (E821) differs from the current Standard Model (SM) prediction by 4.2 standard deviations. In contrast to E821, the goal of the experiment at Fermilab is to deliver a measurement of the anomaly to a precision of 0.14 ppm or less in order to reach more than 5σ discrepancy with the SM and, therefore, strongly establish evidence for new physics. In view of this stringent determination, a thorough description of the delivery, storage, and dynamics of the detected muon beam sets the stage for constraining beam-dynamics driven effects to the muon magnetic anomaly at the ppb level. To that extent, this dissertation introduces the background, principles, and beam requirements of E989; elaborates data-driven numerical models of the Beam Delivery System and Muon q-2 Storage Ring at Fermilab; characterizes the linear and nonlinear dynamics of the muon beam in the storage ring; and describes the contributions to the quantification of the largest beam-dynamics systematic corrections and their uncertainties in the experiment derived from this work.

ACKNOWLEDGMENTS

The following document and the work therein elaborated are not the outcomes of an individual effort. Instead, they bear a resemblance to a song, where I happened to be the soloist of this specific piece while being part of an orchestra made of outstanding interpreters and passionate directors. I am deeply thankful to each of them for all their help.

The primary directors were my research advisors Martin Berz and Mike Syphers. I am deeply indebted to Martin for the scientific guidance over the years and, especially, for teaching me how to be brave against challenges that seemed impossible to resolve. I am profoundly grateful to Mike for having introduced me to the field of beam physics, for all his brilliant lessons and support, and for being a constant inspiration of excellence in both the scientific and human spheres.

Simultaneously, close interactions with Bill Morse and James Mott allowed me to move forward within the Muon g-2 Collaboration. To Bill, I take this opportunity to thank him for all his encouragement from the very beginning, for the golden ideas that contributed to this work, and for constantly sharing his *optics*: "Nature is smarter than us, so we have to be humble!" To James, many thanks for sharing great ideas and skills; it has been a fortune to learn from one of the best.

I also thank Kyoko Makino for sharing her remarkable level of detail and accuracy, which contributed to this work, and all the members of my Ph.D. guidance committee: Wade Fisher, Óscar Naviliat Cuncic, and Chong-Yu Ruan, together with Martin, Mike, and Kyoko. I particularly thank Remco Zegers, the graduate program director of the Department of Physics and Astronomy, for his strong support during the problematic COVID era and Kim Crosslan at MSU for her constant embracement. Many thanks to my graduate school fellows at MSU: Maxwell Cao, Kirill Moskovtsev, Eremey Valetov, and Adrian Weisskopf. I was lucky to have shared my time with them over the last years.

Many scientists and engineers of the Muon g-2 Collaboration at Fermilab made the work described in this dissertation possible. The Tracker, Field, Quad, Kicker, Beam Dynamics, and Phase Acceptance teams provided essential support and experimental data for the analysis presented in this document. In particular, my gratitude goes to Elia Bottalico, Jason Crnkovic, Renee Fatemi, Alejandro García, Joe Grange, Dave Hertzog, Brynn MacCoy, Joe Price, Diktys Stratakis, Erik Swanson, and Volodya Tishchenko.

I am obliged to Bob Zwaska and the Ph.D. Accelerator Program at Fermilab for the generous support over the last years, which allowed me the privilege of having spent at Fermilab the final portion of this experience in close contact with the experiment and scientists therein. Thank you, Susan Winchester and the US Particle Accelerator School, for all the opportunities that are now an essential part of my career. I am thankful to the Office of Science Graduate Student Research, US Department of Energy, and the Dissertation Completion Fellowship, MSU College of Natural Science, for their care.

Most importantly, I cannot thank enough my parents, sister, and my beloved Yeni; without them, nothing is as worthy as it is. Thanks, Father, for your unconditional guidance and countless lessons to aim for happiness and value in life. Thanks, Mother, for your example and pure love. And Yeni, without you, this work would have been impossible and pointless. Everything is for all of you.

I want to thank all the friends I had the pleasure of meeting during graduate school. And to my life-long Colombian friends, thanks for making this journey more fun.

And lastly, thank you, Universe, for enriching and entertaining our lives with so many beautiful and exciting problems to be hopefully understood. This work was supported by the US Department of Energy under Contract No. DE-FG02-08ER41546 and Contract No. DE-SC0018636. This document was prepared using the Fermi National Accelerator Laboratory (Fermilab) resources, a US Department of Energy, Office of Science, HEP User Facility. Fermilab is managed by Fermi Research Alliance, LLC (FRA), acting under Contract No. DE-AC02-07CH11359.

This research used the National Energy Research Scientific Computing Center (NERSC) resources, a US Department of Energy Office of Science User Facility operated under Contract No. DE-AC02-05CH11231.

LIST OF TABLES

4	Recent g -2 values of charged leptons, taken from [17] and [18]. Tensions between g -2 values from experiments and theory have been the main mo- tivation of g -2 experiments.	Table 1.1:
23	Magnet parameters of the g -2 storage ring	Table 1.2:
44	Second-order transfer map of the Delivery Ring. The first five columns correspond to $(x , (a , (y , (b , and (l , whereas the last column indicates (j_1, j_2, \ldots, j_7) in that order. For instance, in the ninth row, first column, the (x xa) coefficient is displayed.$	Table 2.1:
49	Number of protons (p) , muons (μ) , and pions (π) along the BDS (quantities per proton on target).	Table 2.2:
53	Relative difference in pion population at the end of the M3 beamline from fringe field effects, up to fourth-order nonlinear terms, and random misalignments of beamline elements (horizontal and vertical misplacements with standard deviations of 0.25 mm). Statistical errors in the last row are calculated based on numerical simulations with ten different misplacement scenarios, initialized with independent random seeds.	Table 2.3:
53	Relative difference in muon population at the end of the M3, Delivery Ring (after four turns), and M5 beamline sections from fringe field effects, up to fourth-order nonlinear terms, and random misalignments of beamline elements (horizontal and vertical misplacements with standard deviations of 0.25 mm). Statistical errors in the last row are calculated based on numerical simulations with ten different misplacement scenarios, initialized with independent random seeds.	Table 2.4:
68	$a_{k,0}$ coefficients at the main ESQ field region (see Eq. (3.3)) for HV= 18.3 kV, scaled by $r_0^{k+l}/k!l!$ ($r_0 = 5$ cm). Due to the ESQ midplane symmetry, coefficients with odd l values are zero.	Table 3.1:
89	Relative comparisons of computed horizontal tunes with measurements.	Table 3.2:
109	Tune coefficients at HV= 18.3 kV up to fifth order, normalized by 100 ^{order} . For example, $(\nu_x \delta) = -0.13199935.$	Table 3.3:
118	Resonant conditions related to betatron excitations.	Table 3.4:

Table 3.5:	Storage ring nominal admittances for Run-1 ESQ setpoints	132
Table 3.6:	Maximum value ranges in the storage ring along the azimuth for Run-1 settings	132
Table 3.7:	Transverse motion frequencies of the g -2 stored beam (HV= 18.3 kV). The last column indicates cyclotron revolutions per frequency cycle	134
Table 4.1:	The Run-1 beam dynamics corrections [45]. The C_{ml} and C_{pa} corrections are anticipated to be significantly smaller for runs posterior to Run-1 where the ESQ fields are expected to behave stably during data taking. The E- field correction C_e counteracts the largest biasing in ω_a due to additional spin precessions of stored muons away from magic momentum	172
Table 4.2:	ω_a corrections due to muon losses from beam tracking simulations. Errors for each calculation are produced after considering the measured spin- momentum correlation uncertainties and simulation statistical limits	180
Table 4.3:	Main mechanisms of detected-phase drifts. The vertical contribution domi- nates the phase acceptance correction during Run-1 at calorimeters $k = 13$ and $k = 19$ near trackers longitudinal acceptance	188
Table 4.4:	Cases of study for $\langle \Delta \omega_a \rangle$ tracking, from the simple (top) to the detailed model (bottom).	203
Table 4.5:	C_e versus tracking (no vertical betatron motion)	203
Table 4.6:	$C_e + C_p$ versus tracking (full betatron motion)	205
Table 4.7:	Deviations to time-independent C_e corrections during Run-1, based on tracking simulations and optical lattice calculations with the COSY-based model of the g -2 storage ring	209
Table 4.8:	Sensitivity studies of the muon-weighted field to azimuthal beam variations.	226

LIST OF FIGURES

Figure 1.1:	QED vertex perturbative loops represented with Feynman diagrams. The interaction described by Dirac's equation is represented in the 0th-order loop diagram shown in (a). In (b), the first-order loop contributes $\alpha/2\pi$ to a_{μ} [15]. The diagram in (c) represents all the other higher order contributions to a_{μ} of virtual particles coupling to leptons or photons	5
Figure 1.2:	Lowest order (a) and (b) largest EW contributions to a_{μ}^{SM}	7
Figure 1.3:	Feynman diagrams of the LO hadronic vacuum polarization (HVP) and light-by-light scattering (HLbL).	8
Figure 1.4:	Difference between the theoretical (green) and most recent measurements of a_{μ} [28]. The inner tick marks indicate the statistical contribution to the total uncertainties. The theoretical value follows the recommendation from the Muon g-2 Theory Initiative [22]. The ×4 smaller experimental error goal at Fermilab requires twenty times more statistics and systematic uncertainties reduced by a factor of $\simeq 3.$	11
Figure 1.5:	Number of positrons from a highly polarized muon beam ($\mathcal{P} = 0.95$) decaying via $\mu^+ \to e^+ \nu_e \bar{\nu}_\mu$, subject to the positron energy E in the laboratory frame and ignoring the exponential term $e^{-t/\gamma\tau}$. The energy distribution oscillates as the muon beam polarization rotates relative to the beam's direction of motion with an angular frequency ω_a independent of time. The black curve corresponds to the polarization parallel to momentum, whereas the blue and red curves show the energy distribution when these two directions are perpendicular and anti-parallel to momentum, respectively. Arrows on the top-right corner illustrate polarization directions relative to momentum direction (gray), with the same color scheme as the curves. The oscillation is statistically maximized when integrating above ~ 1.8 GeV.	16
Figure 1.6:	Number of positrons above energy threshold detected at Fermilab's muon g -2 experiment, Run-1	17
Figure 1.7:	(a) Straw tracking station and (b) a detector module [38]	20

- Figure 1.9: Cross section of the storage ring magnet. The yoke is made of six layers of magnet steel with an open side to allow for positrons from muon decay to reach the inner side of the ring. A total of twelve of these sections assembled together provide a continuous and ultra-uniform magnetic field within the pole's gap, where the stored muon beam revolves for several thousands of turns. Passive and active shimming via surface currents, thousands of pieces and around the muon storage region, and other movable pieces of the storage ring magnet allow to calibrate and further reduce inhomogeneities of the magnetic field in the storage region [40].
- Figure 1.10: Array of pNMR probes installed in the trolley (white circles), used to periodically measure the magnetic field in the storage region. Fixed probes installed above and below the storage region (shown in Fig. 1.9) are used to interpolate the magnetic field data between trolley runs. The heat map represents a typical sample of the magnetic field from trolley data fitted with a multipole expansion, within the storage region and averaged azimuthally along the ring [39]. The color legend units are Tesla. . . .
- Figure 1.12: Illustrations of the pitch (left) and E-field (right) corrections. The pitch correction emerges mainly from the transverse vertical motion of muons in the lab frame; the standard pitch correction becomes non-negligible at E989 for the typical vertical oscillations maintained by the storage ring (i.e., $\leq 2 \text{ mrad}$ vertical tilt angles relative to the horizontal midplane). In the E-field correction, the spin of muons away from the magic momentum $p_0 = m_{\mu}c/\sqrt{a_{\mu}}$ experiences rotations mostly contained in the transversal plane as expressed in the last term of Eq. (1.30). The momentum acceptance $\delta \sim 0.5\%$ and the electric field, $E_y \sim 6 \text{ kV/cm}$ at 4 cm from the ideal orbit, provided by the Electrostatic Quadrupole stations (ESQ) contribute to an overall vertical precession frequency of about 400 ppb opposite to the nominal g-2 frequency.

Figure 1.13: Sample of the muon spread distribution from Fast Rotation analysis [45]. 30

Figure 1.14:	: Vertical beam profile from the tracking detection system [45]. \ldots .	31
Figure 1.15:	Beam transverse intensity from realistic storage ring simulations, referred as the fast-rotation signal. Due to momentum spread, the range of cy- clotron frequencies causes high- and low-momentum muons to recombine as the beam decoheres in the longitudinal direction. The cyclotron fre- quencies distribution is recovered from a Fourier transform, which yield the momentum spread distribution (see sample in Fig. 1.13) for the E-field correction	32
Figure 2.1:	A schematic layout of the beam delivery system (BDS). Secondary particles (mostly pions, muons, and protons) downstream of the target station at AP0 are canalized through the M2/M3 lines and injected into the Delivery Ring (DR), where protons are discarded and most of the remaining pions decay after four turns. A cleaner beam of mostly muons is extracted to the M4/M5 lines and ultimately delivered to the Muon g -2 Storage Ring (SR).	35
Figure 2.2:	Time structure of the 10^{12} -, 120 ns-pulse train impinging the production target per cycle [55]	35
Figure 2.3:	M2/M3 beta and dispersion functions. The horizontal dispersion (solid green line) originated by the pulsed magnet at the start of the M2 line is canceled out by a switch dipole 50 m downstream, whose large pole width accommodates the beam to enter the M3 line. At around 170 m, the 100 m FODO channel (i.e., an alternating-gradient arrangement of magnetic quadrupoles focusing(defocusing) and defocusing(focusing) in the horizontal(vertical) direction) is interrupted by two horizontal bends (18.3°) to align the optical axis with the downstream beamline and a quadrupole triplet to cancel out horizontal dispersion. On the right-hand side of the plot, the optical functions reflect the geometric and optical matching section to transport the beam to the Delivery Ring, elevated approximately 4 ft above from the M3 line.	37
Figure 2.4:	Number of muons, μ^+ , pions, π^+ , and protons, p^+ , per proton on target (POT) along the M2/M3 beamlines. The horizontal axis represents the longitudinal distance of the optical axis. Main muon losses of about 11% and 20% take place at the 18.5° horizontal bend ($s \sim 160.0$ m) and along the vertical injection upstream of the DR ($s \sim 280.0$ m), respectively. The star-shaped marker around $s \sim 235$ m depicts the number of total particles per POT from measurements (Fig. 3 in [57]).	38

Figure 2.5:	Number of muons, μ^+ , pions, π^+ , and protons, p^+ , per proton on target (POT) along four turns around the Delivery Ring. The design momentum acceptance of 2% reveals naturally in beam tracking simulations when accounting for the beamline apertures present in the DR. All pions decay prior to the third turn along the DR.	40
Figure 2.6:	Beta and dispersion functions at one three-fold symmetric section of the delivery ring (DR) where the longitudinal distance of the beamline is shown in the horizontal axis. Fringe fields modeled in simulations change the beta functions, β_x and β_y , by less than 3%.	40
Figure 2.7:	M4/M5 lattice functions calculated with COSY INFINITY. The design of the M4/M5 beamlines favors losses minimization.	41
Figure 2.8:	Number of muons, μ^+ , per proton on target (POT) along the M4/M5 beamlines. The pale-rose dashed line depicts muons within the muon g -2 storage ring momentum acceptance. For g -2 runs posterior to Run-1, the insertion of passive wedge absorbers in the BDS maximized the muon population within $ \delta < 0.5\%$ to increase the stored beam fraction [62].	42
Figure 2.9:	Momentum spread of the muon beam after four turns around the Delivery Ring. The momentum acceptance sustained at the BDS beamlines allows for the preparation of a highly polarized muon beam (P=0.969 from BDS simulations).	47
Figure 2.10:	Histograms of the normalized muon beam spin components (in natural units) in optical coordinates at the end of M3 (left), Delivery Ring (center), and M5 (right) beamline sections. The polarization projections P_x , P_y , and P_z (parallel to the x , y , and s directions, respectively) are shown inside the thick black frames. As indicated by the projection $P_y = 0$, the high polarization P of the beam is largely contained in the horizontal plane.	49
Figure 2.11:	Simulation results of the number of pions and muons with $ \delta < 2\%$ per POT under up to fourth-order (o4) effects along the M2/M3 lines with fringe fields (FR) turned on. The longitudinal distance along the M2/M3 lines is shown in the horizontal axis. As depicted by the overlapping curves of the muon population for the two o1/o4 cases, linear simulations do not significantly differ from results when high-order terms in the computation of the particle dynamics are simulated	50
Figure 2.12:	Enge function falloff of a typical dipole element in COSY INFINITY, used to represent fringe fields in the BDS simulations. The aperture for this case is equal to 10 cm.	51

Figure 2.13:	Fringe field effects on the population of pions and muons along the de- livery ring (DR). The horizontal axis represents the longitudinal distance corresponding to four consecutive turns in the DR. From the COSY-based BDS model simulations, fringe fields (FR) contribute to maintaining more pions within the apertures of the DR, which consequently increase the population of muons by 9.4% before being extracted to the M4 line. The "o4" abbreviation in the legend denotes the order of the computation (i.e., fourth order)	52
Figure 2.14:	Simulation results of the muon population with $ \delta < 2\%$ under the effects of beamline misalignments along the M4/M5 lines. The number of muons per proton on target (POT) is shown in the vertical axis as a function of the longitudinal distance along the M4/M5 lines. The red line depicts the number of muons for the ideal case of no misalignments present in the beam delivery system. The green band summarizes simulation results for several scenarios of beamline elements randomly misaligned in both vertical and horizontal directions.	54
Figure 2.15:	Histogram of the muon spin projection angle in the horizontal plane with respect to the reference optical axis at the storage ring (SR) en- trance from simulations. The beam delivery system (BDS) is designed to favor the capture of longitudinally polarized muons from pion decay. However, as the muon beam travels through the bending sections of the BDS—especially along the Delivery Ring which houses multiple rectangu- lar bending magnets—the polarization develops a transversal component before the beam is delivered to the g -2 storage ring	55
Figure 2.16:	Beam average of the spin projection angle in the horizontal plane with respect to the reference optical axis, $\langle \varphi_a \rangle$, versus the Lorentz factor, γ , at the exit of the delivery ring after four turns. Simulation results presented in this figure correspond to our COSY-based BDS model with fringe fields turned on.	56
Figure 3.1:	Layout of the Muon g -2 storage ring at Fermilab. The four locations of the ESQ are found next to labels "Q1-Q4" (each covering 39° azimuthally) and labels "K1-K3" indicate the place of the injection kicker plates within the ring. "C" labels denote the beam collimators arrangement	60

Figure 3.2:	Flow chart of the COSY-based Muon Storage Ring Model. Experimental measurements constitute the guide fields as defined in the model, whose main output is nonlinear transfer maps for the calculation of optical lattice functions and beam orbital (and spin) symplectic tracking. With special methods explained in this chapter, guide fields are reconstructed and initial beam distributions are recreated for a detailed characterization of the muon beam in the g -2 storage ring. The characterization is further used for quantifications of beam dynamics systematic corrections in the g -2 final measurement.	63
Figure 3.3:	Photograph of one ESQ station. For vertical confinement of (positive) muons, the top and bottom plates are positively charged whereas the lateral plates are charged with negative voltage. The vertical magnetic field in the storage ring largely contributes to stable motion in the horizontal direction, in spite of the defocusing radial gradient from the ESQ inner and outer plates.	64
Figure 3.4:	Illustration of the HV traces from plates connected to the 1-pulse (red line) and 2-pulse (blue curve) HV supplies. The mis-powered ESQ plates (blue) during the initial $\sim 7 \mu$ s after injection shift the beam towards the limiting apertures of the storage volume, in order to scrape the beam in preparation for the data taking period at $t > 30 \mu$ s	65
Figure 3.5:	Radial electric field along the midplane (HV= 18.3 kV). Near the aperture limits at $x = 45 \text{ mm}$, nonlinearities from the ESQ electric fields distort the otherwise linear radial field.	66
Figure 3.6:	Main electrostatic potential $[kV]$ from an ESQ station on the left side, overlaid with electric vector field represented with arrows. On the right, electrostatic potential from higher order terms in the Taylor expansion; the curvature of the plates and the presence of the 20 pole are manifested near the limiting bounds of the storage region	69
Figure 3.7:	Longitudinal fringe field at an ESQ station edge. The effective field boundary extends the occupancy of the electric fields in the hard-edge view by $\sim 0.436\%$.	70
Figure 3.8:	Magnetic field multipoles from Trolley Run 3956. All the multipole terms are expressed relative to the ideal vertical magnetic field B_0 that sustains magic muons in the ideal orbit. The skew dipole term (also called radial field) was measured with a Hall probe in 2016 [40] and averaged out to recreate the expected effect of the surface correction coils (SCC)	72
Figure 3.9:	Transverse view of a kicker station. The plate geometry is designed to maximize current-to-field conversion in the storage region.	74

Figure 3.10:	Representative kicker strength pulse during the first run of the muon g -2 experiment, measured with a magnetometer	75
Figure 3.11:	Cross section of the magnetic field implemented in the COSY-based model for tracking. The field is stronger near the plate edges and uniform around the center, to deflect muons radially outward.	76
Figure 3.12:	Picture of a collimator inserted around the design orbit	79
Figure 3.13:	Simulated beam distribution at the exit of the inflector, after the final focus to pass the beam through the hole in the backleg iron. The beam is mostly tangential to the design orbit and about 77 mm radially outward at injection.	80
Figure 3.14:	Representative longitudinal profile of the muon beam as measured by the T0 detector. Its length is desired to be contained within the main peak of the kicker pulse to maximize beam storage. The solid line shows the type of multi-Gaussian interpolation used in the model to recreate the longitudinal profile of the simulated muon beam.	81
Figure 3.15:	Radial (black) and vertical (blue) betatron tunes as a function of ESQ voltage	91
Figure 3.16:	Radial (black) and vertical (blue) linear chromaticities as a function of ESQ voltage.	92
Figure 3.17:	Radial α , β , and γ functions at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plots HV = 18.3 kV, whereas HV = 20.4 kV for plots on the right side. Gray shadows depict ESQ sta- tions along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.	94
Figure 3.18:	Vertical α , β , and γ functions at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plots HV = 18.3 kV, whereas HV = 20.4 kV for plots on the right side. Gray shadows depict ESQ sta- tions along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.	95

Figure 3.19:	Radial dispersion function at 5 μ s (red curves), 20 μ s (green curves), and 1000 μ s (black curves). The ESQ voltage is equal to HV = 18.3 kV on the left-side plot, whereas HV = 20.4 kV for the plot on the right side. Inhomogeneities in the normal quadrupole term of the magnetic field break the four-fold symmetry.	96
Figure 3.20:	Vertical dispersion function at $5 \mu s$ (red curves), $20 \mu s$ (green curves), and $1000 \mu s$ (black curves). On the left-side plot HV = $18.3 \mathrm{kV}$, whereas HV = $20.4 \mathrm{kV}$ for the plot on the right side. As the magnetic field is mostly oriented vertically, vertical dispersions are negligible	96
Figure 3.21:	Beta function distortions from magnetic field inhomogeneities at 5 μ s (red curves), 20 μ s (green curves), and 1000 μ s (black curves) for HV = 18.3 kV.	98
Figure 3.22:	Dispersion function distortions from magnetic field inhomogeneities at $5 \mu s$ (red curves), $20 \mu s$ (green curves), and $1000 \mu s$ (black curves) for $HV = 18.3 kV$. The plot on the right side shows the total distortion in the vertical dispersion function, which is equal to zero in the nominal case, whereas on the left side the relative distortion of the radial dispersion function is displayed.	98
Figure 3.23:	Radial closed orbits ($\delta = 0$) at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plot HV = 18.3 kV, whereas HV = 20.4 kV for the plot on the right side. The intentional stretching of the orbit during scraping increases the probability of outermost muons to hit a collimator and, in this way, minimize muon loss rates	102
Figure 3.24:	Vertical closed orbits ($\delta = 0$) at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plot HV = 18.3 kV, whereas HV = 20.4 kV for the plot on the right side. The induced skew dipole ESQ field created from the HV imbalance between the top/bottom plates shifts the vertical closed orbit for beam scraping.	102
Figure 3.25:	Representative closed orbits during the datasets of the first run (Run-1) of the experiment (60h (1a), HK (1b), 9d (1c), and EG (1d)). Fluctuations in temperature affected the dipole terms of the magnetic field, which led to different closed orbits per Run-1 dataset.	103
Figure 3.26:	Amplitude-dependent tune shifts ($\delta = 0$) within the storage region with- out magnetic field imperfections (HV= 18.3 kV). The horizontal axis cor- responds to radial betatron amplitudes and the vertical axis represents vertical amplitudes	107

Figure 3.27:	Amplitude-dependent tune shifts ($\delta = 0$) within the storage region with magnetic field imperfections (HV= 18.3 kV). The horizontal axis cor- responds to radial betatron amplitudes and the vertical axis represents vertical amplitudes	107
Figure 3.28:	Momentum-dependent tune shifts (no betatron amplitudes) with and with- out magnetic field imperfections (HV= 18.3 kV). Nonlinear shifts take place for $ \delta > 0.2\%$, inside the momentum acceptance	108
Figure 3.29:	Beam radial de-coherence with (left) and without (right) tune shifts at the readout location of the straw tracking detector (station 12). As a reference, data from the tracker is shown in red. The two plots on top display radial beam centroids, whereas the bottom plots correspond to radial beam widths	110
Figure 3.30:	Fraction of muon losses between $121 - 186 \mu s$ after beam injection with the COSY-based model for several ESQ configurations. Measurements [94]— shown in arbitrary units—result from detections of minimum ionizing particles that deposit ~ 170 MeV of energy in two adjacent calorimeters while two collimators were inserted to the storage region	111
Figure 3.31:	An illustration of resonant tune lines and operating points (i.e., ESQ nom- inal voltages) of the g-2 storage ring. The high-voltage applied to the ESQ plates to set operating points are shown next to resonances predicted by numerical studies with the COSY-based ring model. Measurements of lost muons have revealed resonance peaks at $\sim 13.1, 16.8, 18.6, \text{ and } 21.1 \text{ kV}$ as well (see Fig. 3.30). Lost muons measurements have not been performed for higher ESQ voltages. Red markers show the operating points used in Run-1	113
Figure 3.32:	With the tune shifts readily available from the COSY-model, momentum and normal form radii of stored muons from a realistic initial distribu- tion as described in Sec. 3.2.5 are used for the calculation of the tune footprint. The ESQ setpoint is 18.3 kV. Due to nonlinear amplitude- and momentum-tune shifts, a considerable fraction of the stored muons is affected by the resonance around in tune space, especially the $3\nu_y = 1$ res- onant condition driven by the skew magnetic sextupole term. Red(blue) markers indicate high(low) density of entries in the tune footprint	115
Figure 3.33:	Fraction of muon losses from simulations during the time interval $121 - 186\mu$ s after beam injection. Configuration details are listed on page 116. The bottom figure depicts lost muon fractions with a reduced vertical range to discern losses when magnetic field imperfections are not accounted for.	117

Figure 3.34:	On the left, magnetic skew sextupole coefficient a_2 as measured by NMR probes. On the right plot, Fourier decomposition of the coefficient a_2 in azimuthal harmonics $a_2 = \sum_{N=0}^{n} a_{2,N} \cos(N\theta + \phi_N)$. The $N = 1$ term, which is the main driver of the resonant condition $3\nu_y = 1$, is depicted in green color.	119
Figure 3.35:	Lost muons fraction over a muon lifetime after the scraping stage is com- pleted. In red (triangular markers), all the magnetic multipole terms are turned on during the beam tracking simulation, whereas in blue (dia- mond markers), these are turned off. In subsequent simulations, it was found that only the magnetic skew sextupole term from measured field inhomogeneities was sufficient to drive the betatron-resonance peak at $HV \approx 18.6 \mathrm{kV}.$	120
Figure 3.36:	Phase space coordinates and maximum excursion of a muon not lost (reference case)	122
Figure 3.37:	Trajectories in phase space of three different muons (distinguished by color) in the linear regime	123
Figure 3.38:	Maximum excursions of three lost muons in the linear regime. \ldots .	124
Figure 3.39:	Tunes of three lost muons in the linear regime. Note the proximity between the red and black entries (the red marker partially covers the marker in black color)	125
Figure 3.40:	Trajectories in phase space of three different muons (distinguished by color) in the nonlinear regime	126
Figure 3.41:	Maximum excursions of three lost muons in the nonlinear regime	127
Figure 3.42:	Tunes of three muons in the nonlinear regime before getting lost. \ldots	128
Figure 3.43:	Muon loss fractions with nonlinearities (black curve) and without them (gray curve) from symplectic tracking, COSY-based, beam simulations. The ESQ setpoint was 18.3 kV, two collimators were inserted, and both cases start with the same data-based initial distribution. Muon loss rates are highly affected by nonlinearities of the guide fields	129
Figure 3.44:	Stroboscopic tracking in the vertical phase space illustrating orbit behav- ior with two period-3 fixed point structures present [101], for ESQ voltage at 18.3 kV. Trajectories in blue and green colors are examples of muons (within the ring admittance and momentum acceptance) with highly mod- ulated vertical amplitudes. Picture by courtesy of Adrian Weisskopf	129

Figure 3.45:	igure 3.45: Muon loss rates from several tracking simulations (HV=18.3 kV). The effect of damaged resistors and the effect from symplectic enforcement during tracking is shown	
Figure 3.46:	Qualitative comparison between stored muon rates from simulations (gray) at $t = 186 \mu\text{s}$ after beam injection and measured relative positron rates (arbitrary units) from stored muon decays [107]. Error bars correspond to standard errors of the multiple numerical analyses for each ESQ voltage configuration. As the vertical and radial admittances increase and decrease, respectively, proportional to the ESQ voltage, the fraction of stored muons increases, reaching a plateau at 22 kV where the stored fraction starts to become more sensitive to the radial admittance. The low fraction of stored muons is a consequence of the momentum spread being about two times larger than the momentum acceptance, the dispersion mismatch between the end of the M5-line and the storage ring, and the imperfect kicks purposed to inject the beam	131
Figure 3.47:	Long-term radial beam de-coherence	134
Figure 3.48:	Long-term vertical beam temporal modulations.	135
Figure 3.49:	Beam frequencies extracted with FFT from centroids motion	136

Figure 3.58:	Typical Run-1 momentum time beam distribution from Run-1 tracking simulation.	143
Figure 3.59:	Projections of the typical Run-1 momentum time beam distribution from Run-1 tracking simulation	143
Figure 3.60:	Radial CBO frequencies during the four Run-1 datasets from straw track- ing detectors data. Semi-transparent markers are obtained from sliding sinusoidal fits $(\pm 5 \mu s)$ to the recorded radial beam centroid, whereas solid lines result from multi-parameter fits through the entire fill. Both methods are equivalent.	145
Figure 3.61:	Vertical centroid drifts during Run-1 from straw tracking detectors data. Solid lines are fits with double exponential terms and a constant part as the functional form.	146
Figure 3.62:	Single-CADDOCK high-voltage resistor (top) and chain of potted HV resistors (bottom). Two of the latter type of resistors became damaged during Run-1.	147
Figure 3.63:	HV-traces sample (circle markers) from HV probe measurements in September 2018, at Q1L plates connected to the damaged resistors. Blue and red lines depict nominal HV traces.	148
Figure 3.64:	High voltage on Q1LT and Q1LB plates (left) and objective function (right) per iteration as the optimization takes place for the Run-1, EndGame dataset, at 40 μ s. The optimizer supported by COSY INFINITY (i.e., the generalized least squares Newton method) fits Q1LT/Q1LB HVs such that the COSY-based storage ring model with damaged resistors accounted for reproduces a vertical fixed point (equivalent to the vertical mean) and CBO frequency as measured by tracker station 12.	152

Figure 3.65:	Reconstructed HV traces (normalized to their nominal voltage set-points) at Q1L during Run-1 datasets. Dashed and solid lines correspond to Q1LT and Q1LB plates, respectively.	152
Figure 3.66:	Comparisons between tracker data (blue markers) and tracking simula- tions (red markers) at tracker S12 azimuthal readout location with the damaged-resistors effect implemented. On the left is the CBO frequency, whereas on the right vertical centroids are shown. Similarly, strong agree- ments are obtained for the other Run-1 datasets. For comparison pur- poses, the vertical entries on the right plot are shifted within tracker mis- alignment errors	153
Figure 3.67:	Black markers are vertical beam drifts (40-300 μ s) from calorimeter data (energy threshold of 1.7 GeV) under material-effect corrections, where double exponential fits were employed. In blue, vertical closed orbit distortion drifts from 40-300 μ s using the COSY-based model with the reconstructed HV traces implemented. The blue error band is an estimate of the uncertainty introduced by the vertical dispersion. The red squares are from a GM2RINGSIM muon tracking simulation [45] with an implementation of the electric guide fields reconstructed with the COSY-based model. The simulations are matched to data by associating the closed orbit placed ~ 22° upstream of the calorimeter position.	154
Figure 3.68:	Vertical closed orbits at 30 μ s (red curves), 100 μ s (blue curves), 200 μ s (green curves), and 300 μ s (black curves) during Run-1. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.	156
Figure 3.69:	Vertical beta functions at $30 \ \mu s$ (red curves), $100 \ \mu s$ (blue curves), $200 \ \mu s$ (green curves), and $300 \ \mu s$ (black curves) during Run-1.	157
Figure 3.70:	Radial beta functions at $30 \mu s$ (red curves), $100 \mu s$ (blue curves), $200 \mu s$ (green curves), and $300 \mu s$ (black curves) during Run-1.	158
Figure 3.71:	Radial dispersion functions at $30 \mu s$ (red curves), $100 \mu s$ (blue curves), $200 \mu s$ (green curves), and $300 \mu s$ (black curves) during Run-1.	159
Figure 3.72:	Relative vertical beta functions drift from 30 μs to 1000 $\mu s.$	160
Figure 3.73:	β_x, β_y, D_x , and vertical closed orbit at 210° from the upstream entrance of station Q1S for dataset Run-1d.	161

Figure 3.74:	Beam drifts from 40 µs to 300 µs anchored to tracker data for the Run- 1d dataset. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. With the Run-1 optical lattice functions, the observed beam drifts measured by the muon g-2 straw tracking detectors are projected along the entire azimuth of the storage ring.	162
Figure 3.75:	Resolution- and acceptance-corrected radial position versus time from tracker data, Station 12. By reconstructing the trajectory of decay positrons detected by the tracking planes, muon decay positions are extrapolated. Coherent oscillations are a consequence of the beam injection process	163
Figure 3.76:	Reconstructed beam distribution in the radial direction. On the left plot, the upper limits are determined by the physical apertures of the collimators which bound maximum radial excursions, whereas the maximum kicker strength defines the lower limits.	164
Figure 3.77:	Muon beam intensity from simulation (left) and tracker data (right), station 12, during Run-1a from $30 \mu s < t < 300 \mu s$.	165
Figure 3.78:	Muon beam intensity projections from simulation (red) and tracker data (blue), station 12, during Run-1a from $30 \mu s < t < 300 \mu s$	166
Figure 3.79:	Radial beam evolution over time from tracker S12 data (top) and simulated beam (bottom) during Run-1a. The data-driven reconstruction of the initial beam conditions allows to capture in beam tracking simulations (in this case with the COSY-based model) the transverse and temporal evolution of the observed beam.	166
Figure 3.80:	Radial CBO frequencies from simulated beam (red) and tracker data (blue) for each Run-1 dataset	167
Figure 3.81:	Vertical centroid from simulated beam (red) and tracker data (blue), sta- tion 12 for each Run-1 dataset.	168
Figure 4.1:	Momentum dependence of the initial g -2 phase φ_0 . The simulations (black plot markers) are in good agreement with experimental data (blue, preliminary). The experimental data were obtained by studying the behavior of muons with momenta above and below the magic momentum in the storage ring [118]	175
Figure 4.2:	Momentum spread over time from Run-1d tracking simulations at early and late times. While the beam spreads in the longitudinal direction, muons with different momenta combine together.	176

Figure 4.3:	Muon loss rates versus time, 30 µs after injection, from symplectic tracking Run-1 simulations (left) and data (right, [119]). The $3\nu_y = 1$ resonance nearby Runs 1a and 1d increases the loss fraction (Sec. 3.4.3). Uncertainty bands on the curves from data accounts for experimental scaling errors in the determination of muon loss rates	176
Figure 4.4:	Relative momentum offsets of lost muons from Run-1 symplectic tracking simulations ($30 \ \mu s < t < 300 \ \mu s$). The vertical axis indicates the number of lost muons (in arbitrary units) per bin of momentum offset	178
Figure 4.5:	Stored beam's average momentum offset, relative to magic momentum, over time from tracking simulations with the COSY-based model	178
Figure 4.6:	g-2 phase time evolution from Run-1 symplectic tracking simulations driven by lost muons. The beam injection scheme and operational set-points lead to different functional forms per Run-1 dataset.	179
Figure 4.7:	Typical detected-phase $\varphi_{0,k}$ (left) and calorimeter acceptance $\varepsilon_{c,k}$ (right) maps from GM2RINGSIM [44]. In the phase map, values indicated by the color legend (in mrad) are relative to a central g-2 phase defined at injection. 1 µrad phase shifts over a muon lifetime in the laboratory frame induce ω_a shifts of about 10 ppb	181
Figure 4.8:	On the left side, the phase $\varphi_0^{c_{13}}(t)$ from the COSY-based Run-1a simulated beam and GM2RINGSIM maps (T-Method) via Eq. (4.12). On the right, the phase drift extracted from non-randomized window fits (black markers), which effectively capture the phase drift without the modulation induced by the beam coherent oscillations shown on the left plot. The red curve is a single-exponential fit to the resulting phase drift without modulation.	184
Figure 4.9:	Extracted drifting phases from all extraction methods. On the left, all methods agree when detector acceptance is absent. On the right plot, the randomized method does not capture the phase drift from radial CBO de-coherence, which emerges under the presence of nonuniform detector acceptance.	186
Figure 4.10:	ω_a shifts due to phase acceptance corrections mediated by the different phase drift extraction methods, without (left) and with (right) detector acceptance. Monte Carlo $N(t)$ histograms are generated with the drifting phases accounted for to extract the corresponding ω_a shifts. In gray, results from the raw phase $\varphi_0^{\text{calo}_{13}}(t)$ without drift extraction are shown. The removal of phase drifting induced by the radial CBO de-coherence from the randomized method is clearly visible in the right plot	187

Figure 4.11:	Phases $\varphi_0^{c_k}(t)$ (left) and their corresponding phase drifts (on the right) from the non-randomized, window fits method. The two plots on top correspond to a detected phase at calorimeter $k = 13$ from vertical beam drifting. In the middle, phase changes are driven by slow radial beam motion. At the bottom, phase drifting due to radial CBO de-coherence. Fits in red are performed to extract drift amplitudes	190
Figure 4.12:	Drifting phase amplitudes from single-exponential fits to phase drifts (ex- tracted from non-randomized, sliding window fits) induced by vertical beam motion. In red, scaling of the phase amplitude at calorimeter $k = 3$ with vertical beam width drifts only.	193
Figure 4.13:	Drifting phase amplitudes from single-exponential fits to phase drifts (ex- tracted from non-randomized, sliding window fits) induced by radial slow beam drifts. In red, scaling of the phase amplitude at calorimeter $k = 3$ with radial beam centroid drifts only	194
Figure 4.14:	Drifting phase amplitudes from single-exponential fits to phase drifts (ex- tracted from non-randomized, sliding window fits) induced by radial CBO de-coherence. Variations are largely caused by calorimeter acceptances, which exhibit a characteristic azimuthal pattern owing to the instrumen- tation between the storage volume and the calorimeter detectors (see Fig. 4.15).	194
Figure 4.15:	Convolution of total intensities detected by each calorimeter (T-Method) using the COSY-based Run-1a simulated beam and GM2RINGSIM acceptance maps. The formula on the top-left corner indicates the weighting of the beam intensity with muon detection efficiency.	195
Figure 4.16:	Relative ω_a shifts induced by each of the drifting phase mechanisms, separated and combined. The largest shifts are produced by beam drifts of the vertical width.	196
Figure 4.17:	ω_a shifts induced by phase-acceptance drifts from experimental data (Run- 1d) [44]. The Run-1d COSY-based optical lattice functions and per- calorimeter maps from GM2RINGSIM (T-Method) are utilized to calculate all the precession corrections from phase drifts extracted with the ran- domization method. Run-1a simulated beam (semi-transparent colors) and reconstructed pro-		
files (solid colors). The small contributions from the skew octupole and		

files (solid colors). The small contributions from the skew octupole and decapole projections are not well transformed in the reconstruction. . . . 227

Chapter 1

Introduction

Our current understanding of elementary particles from which the physical Universe is made, and the interactions among them, has led to the Standard Model of particle physics (SM). Nearly all the constituent parts of this theory and its implications have been validated experimentally over the last five decades, being the observation of the Higgs boson at CERN's Large Hadron Collider (LHC) a contemporaneous example. Despite its remarkable success, the evidence of physics beyond the frontiers of the Standard Model (e.g., the hierarchy problem and dark matter) demands high-precision completeness tests. In particular, the muon's g-factor, or equivalently the anomalous magnetic moment $a \equiv (g - 2)/2$, has served as a sensitive physical quantity for this purpose. A known discrepancy between experimental measurements and the Standard Model prediction of the muon's anomalous magnetic moment " a_{μ} " would serve as unambiguous evidence of as yet undiscovered particles beyond the Standard Model and perhaps validate or disprove other theoretical models beyond the SM.

The Muon g-2 Experiment at Fermilab (E989) aims at measuring the anomalous magnetic moment of muons with total statistical and systematic fractional errors of 140 ppb or less. This experiment is the consummation of a series of experiments initiated in 1957 [1], in which longitudinally polarized muons from the $\pi \to \mu \to e$ weak-decay channel offer a path to determine the anomalous magnetic moment. Over this period of time, several machines—i.e., cyclotrons [2,3], a synchrocyclotron [4,5], and storage rings [6–8]—have been employed for this purpose. The objects of study of this dissertation are the beam dynamics at the Muon g-2 Storage Ring and, additionally, the Beam Delivery System (BDS) that produces the highly polarized muon beam at Fermilab. Specifically, the combination of high-fidelity numerical models, mathematical methods, measurements, and data analysis detailed throughout Chaps. 2-4 allowed for a detailed beam performance analysis during the commissioning stages of the BDS and beam measurements understanding, operational characterization of the g-2 storage ring, and quantifications of systematic corrections.

The following sections of this chapter introduce the main concepts concerning the muon's anomalous magnetic moment, as well as the experimental technique implemented at Fermilab's g-2 experiment for the determination of a_{μ} ; at the end, the beam dynamics requirements to achieve the goals of the muon g-2 experiment are discussed.

1.1 The Anomalous Magnetic Moment

In classical electrodynamics [9], the magnetic field associated to localized and steady current distributions \boldsymbol{j} at an observation point r far outside from the source can be expressed as a Taylor expansion, where the non-zero leading term yields¹

$$\boldsymbol{B}(\boldsymbol{r}) = \nabla \times \left(\frac{\mu_0}{4\pi} \frac{\boldsymbol{m} \times \boldsymbol{r}}{r^3}\right). \tag{1.1}$$

The term μ_0 corresponds to the magnetic permeability, whereas the vector \boldsymbol{m} is the magnetic dipole moment (or magnetic moment within this context)

$$\boldsymbol{m} = \frac{1}{2} \int d^3 r \, \boldsymbol{r} \times \boldsymbol{j}(\boldsymbol{r}). \tag{1.2}$$

¹SI units are used throughout this document, unless otherwise specified.

A particle with charge q, mass m, and located at r' has an associated current density of

$$\boldsymbol{j}(\boldsymbol{r}) = q\boldsymbol{v}\delta(\boldsymbol{r} - \boldsymbol{r'}). \tag{1.3}$$

Thus, its orbital magnetic moment in terms of the orbital angular momentum $L' = mr' \times v$ can be defined as

$$\boldsymbol{m}_L = \frac{q}{2m} \boldsymbol{L}'. \tag{1.4}$$

This proportionality between the dipole moment and angular momentum remains in the domain of quantum mechanics. From the union between special relativity and quantum mechanics, Dirac's equation of a "S" spin-1/2 elementary particle (e.g., electrons, muons, and taus) under the influence of an external electromagnetic field [10] predicts a spin magnetic moment equal to

$$\boldsymbol{m}_S = g \frac{q}{2m} \boldsymbol{S}.$$
 (1.5)

Within the realm of Dirac's equation, the g-factor in Eq. (1.5) is exactly equal to 2. This theoretical achievement successfully explained early spin measurements such as the Stern-Gerlach experiments [11] from which, in spin terms proposed for the first time by Compton [12] and Uhlenbeck-Goudsmit [13], the g-factor of the electron was found to be $g \approx 2$ [14].

However, as the precision g-factor measurements increased over the years, deviations of fractions of a percent away from Dirac's prediction g = 2 were clearly observed in hyperfine-structure and subsequent experiments [15, 16]. Table 1.1 shows recent experimental g-2 values of charged leptons.

With g-factors being initially contrasted with Dirac's equation, it became customary since then to refer to the relative deviation from the g = 2 expectation back then as the *anomalous*

Table 1.1: Recent g-2 values of charged leptons, taken from [17] and [18]. Tensions between g-2 values from experiments and theory have been the main motivation of g-2 experiments.

	<i>g</i> -2	Relative uncertainty
e	$0.002 \ 319 \ 304 \ 361 \ 82(52)$	2.6×10^{-13}
μ	$0.002 \ 331 \ 841 \ 8(13)$	6.3×10^{-10}
au	-0.036(34)	1.8×10^{-2}

magnetic moment, namely:

$$a \equiv \frac{g-2}{2}.\tag{1.6}$$

Nowadays, the origins of the "anomalous" magnetic moment are explained to a more detailed extent by accounting for radiative corrections within the Standard Model of particle physics framework, as presented next. In particular, the SM prediction of the muon's anomalous magnetic moment relevant for the goals of the muon g-2 experiment at Fermilab is summarized.

1.1.1 Muon g-2 from the Standard Model

In essence, the Standard Model encompasses *all* known contributions to a_{μ} from quantum fluctuations in the form of intermediate elementary particles, i.e., radiative corrections. As the muon's spin-1/2 field interconnects with the external electromagnetic field as theorized by quantum electrodynamics (QED), perturbation theory allows for a serial loop-by-loop description of the corresponding muon-photon interaction in the SM. Each of these loops can be represented via Feynman diagrams as shown in Fig. 1.1, where intermediate (or virtual) particles contribute to the muon-photon interaction,² also known as the QED vertex.

The anomalous magnetic moment is calculated from the Standard Model from the ma-

²It is customary to dub anti-muons (μ^+) as "muons" in the Muon g-2 Collaboration. The same convention is adopted throughout this document.

Figure 1.1: QED vertex perturbative loops represented with Feynman diagrams. The interaction described by Dirac's equation is represented in the 0th-order loop diagram shown in (a). In (b), the first-order loop contributes $\alpha/2\pi$ to a_{μ} [15]. The diagram in (c) represents all the other higher order contributions to a_{μ} of virtual particles coupling to leptons or photons.

trix element describing the physical process within the loop. In general, it contains two independent form factors that specify the parameters of the interaction (see Fig. 1.1(c)). Specifically, for higher order loops, the SM predicts that in the limit of the photon's momentum being zero in the QED vertex, one of these form factors directly defines the anomalous magnetic moment. Thus, by renormalizing the QED vertex with the perturbative higher order terms, a precise calculation of a_{μ} is established from the theory side. It is worth mentioning that the higher order loops contribute to a_{μ} in proportion to the virtual particle and muon masses, m_V and m_{μ} respectively, as $(m_{\mu}/m_V)^2$. Even though electrons are more accessible in the laboratory than muons, the latter are preferred since—given the muon-toelectron ratio $(m_{\mu}/m_e)^2 \approx 4.3 \times 10^4$ —they are four orders of magnitude more sensitive to interactions with heavier virtual particles.

The theoretical contributions to a_{μ} from the Standard Model are typically characterized as follows:

$$a_{\mu}^{SM} = a_{\mu}^{QED} + a_{\mu}^{EW} + a_{\mu}^{HVP} + a_{\mu}^{HLbL}, \qquad (1.7)$$

where a_{μ}^{QED} and a_{μ}^{EW} result from quantum electrodynamics and electroweak interactions, respectively. The other two terms, a_{μ}^{HVP} and a_{μ}^{HLbL} , are the hadronic vacuum polarization and hadronic light-by-light contributions which make up the contribution from hadronic interactions. Next, each of these components is discussed.

The QED contribution: a_{μ}^{QED}

Quantum electrodynamics encapsulates about 99.994% of the a_{μ}^{SM} prediction and results from lepton and photon interactions. Schwinger calculated the first-order loop [15] (see Fig. 1.1(b)) contribution $a_{\mu}^{QED,1}$ in terms of the fine structure constant $\alpha = e^2/4\pi$ (in natural units where $\varepsilon_0 = c = \hbar = 1$):

$$a_{\mu}^{QED,1} = \frac{\alpha}{2\pi} \approx 0.00116.$$
 (1.8)

The other non-dominant higher order terms are further calculated with higher powers of α , comprising contributions from more involved loops where numerous virtual lepton-photon interactions take place. Expressed as a perturbation expansion,

$$a_{\mu}^{QED} = a_{\mu}^{QED,1} + \sum_{n=2}^{\infty} a_{\mu}^{(2n)} \left(\frac{\alpha}{\pi}\right)^n.$$
(1.9)

Since $|\alpha| \ll 1$, the contribution to a_{μ}^{QED} becomes negligible for higher *n* orders.

Kinoshita *et al.* undertook the exceptional effort of computing up to tenth-order QED contributions [19], where over 12,000 Feynman diagrams containing up to 5 loops were involved:

$$a_{\mu}^{QED} = 116584718.931(104) \times 10^{-11}.$$
 (1.10)
The result in Eq. (1.10)—limited by the measurement of α —has been verified independently and is well established, contributing to the associated δa_{μ}^{SM} error the smallest amount.

The contribution from electroweak interactions: a_{μ}^{EW}

Contributions to a_{μ}^{SM} from electroweak interactions account for the smallest value among the other forces. Being mediated by the exchange of charged W, Z, and H neutral bosons as shown in Fig. 1.2, the relatively large masses lead to terms suppression (i.e., 0.0001% of a_{μ}^{QED}). In Fig. 1.2, leading order (LO) EW processes are shown; Feynman's diagram

Figure 1.2: Lowest order (a) and (b) largest EW contributions to a_{μ}^{SM} .

(a) illustrates the exchange of a virtual Z^0 or H^0 boson, closely resembling the LO QED interaction. On the other hand, the interaction depicted in Fig. 1.2(b) corresponds to the emission and recapture of a positively charged W boson and a muon neutrino, being the largest contribution to a_{μ}^{EW} . The LO contributions from W and Z bosons result to be:

$$a_{\mu}^{EW(LO)} \approx \frac{G_F m_{\mu}^2}{8\sqrt{2}\pi^2} \frac{1}{3} \left[2 + \left(\frac{m_W}{m_Z}\right)^2 \right],$$
 (1.11)

where G_F is Fermi coupling constant. Processes with Higgs-boson exchange are negligible due to its relatively large mass. Second-order EW processes make up a small component part of a_{μ}^{EW} , of about -40×10^{-11} [20]. In total [21],

$$a_{\mu}^{EW} = 153.6(1.0) \times 10^{-11}. \tag{1.12}$$

The contribution from hadronic interactions: $a_{\mu}^{HVP} + a_{\mu}^{HLbL}$

In QED, the Standard Model is compelling in calculating processes to energy scales of interest, and the perturbation expansions largely converge. Nevertheless, when the contribution involves quantum chromodynamics (QCD) interactions via quarks, a power expansion in terms of the strong coupling constant α_s alone does not lead to convergence at low energies. Consequently, hadronic contributions to a_{μ}^{SM} dominate its uncertainty. Hadronic processes relevant in this context are typically broken into two components, namely, the hadronic vacuum polarization (HVP) and light-by-light (HLbL) terms (a_{μ}^{HVP} and a_{μ}^{HLbL} , respectively).

The lowest order HVP diagram shown in Fig. 1.3 dominates the hadronic contribution and its associated error. Virtual hadron energies in these processes are below the perturbative

Figure 1.3: Feynman diagrams of the LO hadronic vacuum polarization (HVP) and lightby-light scattering (HLbL).

region of QCD (pQCD). For this reason, dispersion relations (R) from experimental data are

required in addition to pQCD in order to calculate the LO hadronic contribution to a_{μ}^{SM} :

$$a_{\mu}^{HVP,LO} = \left(\frac{\alpha m_{\mu}}{3\pi}\right)^2 \int_{m_{\pi}^2}^{\infty} K(s)R(s)ds \quad \text{for} \quad R \equiv \frac{\sigma_{tot}(e^+e^- \to \text{hadrons})}{\sigma(e^+e^- \to \mu^+\mu^-)}, \tag{1.13}$$

where s is the energy $(E = \sqrt{s})$, K(s) a known function, and σ 's are cross sections. In Eq. (1.13), perturbative QCD can be used at larger energies instead of data-driven input. A number of experiments—BaBar, BELLE, KLOE, VEPP, and BES³— provide the experimental data to calculate the cross sections for all final states [23, 24]. The leading HVP contribution comes from the $\pi^+\pi^-$ channel, and yields in total [22]:

$$a_{\mu}^{HVP} = 6845(40) \times 10^{-11}. \tag{1.14}$$

In the light-by-light hadronic contribution to a_{μ}^{SM} , processes involving four virtual photons coupled to a hadronic state as shown in Fig. 1.3(b) are computed. Since no aid from data-driven dispersion relations as for the HVP contributions can be applied to HLbL interactions, low-energy hadronic models with relatively large associated errors are needed [20]. HLbL terms represent around 2% of the overall hadronic a_{μ} -contribution; however, it accounts for about 40% of its error. A contemporaneous value for HLbL contributions to a_{μ}^{SM} was established by a collaboration of theorists under the name "Glasgow consensus" [25]. In it, several alternative and model-dependent approaches were accounted for, and a detailed discussion of the consensus can be found in [20]. The accepted value from HLbL processes is [26]:

$$a_{\mu}^{HLbL} = 92(18) \times 10^{-11}.$$
 (1.15)

³Detailed references to these experimental efforts can be found in [22].

Another strategy for quantifying hadronic effects is lattice QCD [22]; an established method for first-principle calculations of certain simple hadronic observables. However, HVP is a multi-scale quantity and hence not as simple as other quantities for which lattice calculations have been performed with sub-percent precision. The SM contributions aforementioned follow the guidance from the Muon g-2 Theory Initiative [22] of a reliable theory prediction.

The above component parts of a_{μ}^{SM} are added together to encapsulate from the theory side

$$a_{\mu}^{SM} = 116591810(43) \times 10^{-11}. \tag{1.16}$$

With this prediction determined to a relative precision of 369 ppb, the search for tensions between a_{μ}^{SM} and the experimental muon's anomalous magnetic moment embodies the spirit of Fermilab's muon g-2 experiment. Next, contemporaneous comparisons between theoretical and experimental anomalous magnetic moments of the muon are presented.

1.1.2 Muon g-2: Theory versus experiment

The symbiosis between theoretical formulations posterior to Dirac's g = 2 prediction and experimental measurements of g-factors has been the main driver of muon g-2 experiments during the last decades [1], culminating in the Muon g-2 experiment at Fermilab. After Schwinger, motivated by observations of an unexpectedly large hydrogen's hyperfine structure [15], formulated the first radiative correction of the g-factor beyond Dirac's equation, the work proposed by Lee and Yang on parity violation from decays mediated by the weak force [27] paved the way to go beyond g = 2 with muons from the experimental front. Since then, a consecutive series of experimental and theoretical improvements has led to the tension between the world average measurement and the prediction shown in Eq. (1.16) that Fermilab's g-2 experiment aims to settle down.

Figure 1.4 shows the tension between recent SM predictions of a_{μ} together with the measurement performed at Brookhaven National Laboratory (BNL) from years 1997 to 2001 [8] and the latest measurement at E989 from 2018 (i.e., Run-1) [28]. Fermilab result is the most

Figure 1.4: Difference between the theoretical (green) and most recent measurements of a_{μ} [28]. The inner tick marks indicate the statistical contribution to the total uncertainties. The theoretical value follows the recommendation from the Muon g-2 Theory Initiative [22]. The ×4 smaller experimental error goal at Fermilab requires twenty times more statistics and systematic uncertainties reduced by a factor of $\simeq 3$.

precise measurement of the anomalous magnetic moment of the muon. The experimental technique employed during this experiment, presented in Sec. 1.2, followed the same principles as in the g-2 experiment at BNL. With a combined precision of 350 ppb from E821 and the first E989 measurement (Run-1), the experiment average is

$$a_{\mu}^{Exp} = 116592061(41) \times 10^{-11}.$$
 (1.17)

The experimental result deviates from the current theoretical by a significance of 4.2σ , being

 σ the fractional error associated to the difference [22]

$$\Delta a_{\mu} = a_{\mu}^{Exp} - a_{\mu}^{SM} = (251 \pm 59) \times 10^{-11}.$$
(1.18)

Consequently, the result prompts numerous formulations beyond the Standard Model and further experiments toward explaining and validating the discrepancy.

From the theoretical side, a first lattice result at sub-percent precision (~ 0.7%) was reported by the BMW Collaboration [29] at the time of this dissertation. Their result is in 2σ tension with the data-driven evaluation, but with a systematics-dominated uncertainty. Independent lattice calculations with comparable errors are required in order to test and validate the results, due to the intricacy of the computations needed for these efforts. These calculations are a high priority for the Theory Initiative, thus, are expected to take place in the near future [22].

From the experimental side, the muon g-2 experiment at Fermilab was proposed to reduce BNL's experimental error by a factor of about 4 (see Fig. 1.4), allowing for a significance in the discrepancy more prominent than 5σ —if the central theory and experiment values remain unchanged—that could lead to fundamental breakthroughs. This amount of data is expected to be collected and analyzed by the fiscal year 2023.

1.2 The Muon g-2 Experiment at Fermilab: Experimental Method

In the search for evidence of new physics, muon g-2 experiments have made use of longitudinally polarized muons to measure their anomalous magnetic moment. Fermilab's muon g-2 experiment (E989) aims at extracting this quantity experimentally by counting the number of high-energy positrons over time from the $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$ weak-decay channel. With the same (and significantly upgraded) machine and concept employed at the muon g-2 experiment at Brookhaven National Laboratory (BNL) [8], a highly polarized muon beam produced along the Muon Campus as part of Fermilab's accelerator complex (see Chap. 2) is injected into a storage ring [30] (see Chap. 3). The muon beam circulates the storage ring for hundredths of microseconds until all of them have decayed. At the same time, specialized detection systems measure positrons from muon decay and characterize the injected beam and magnetic guide field for systematic error assessment.

In this section, the experimental technique to measure the anomalous magnetic moment of the muon is presented. A brief overview of the systems directly involved in the experimental technique and beam dynamics measurements is also included. The other components of the g-2 storage ring are presented in Chap. 3 together with corresponding numerical models of them for beam dynamics studies and beam tracking simulations.

1.2.1 The anomalous muon precession frequency ω_a

Ideally, muons with magic momentum $p_0 = m_{\mu}c/\sqrt{a_{\mu}}$ perfectly injected into the g-2 storage ring would circulate around centered orbits of radius $r_0 \approx 7.112 \,\mathrm{m}$, perpendicular to a perfectly uniform vertical magnetic field $\vec{B}_0 = (p_0/er_0) \hat{y}$. Under such circumstances, the spin and cyclotron frequencies [30], $\vec{\omega}_s$ and $\vec{\omega}_c$ respectively, at which the muon's spin and momentum rotate in the laboratory frame would be equal to

$$\vec{\omega}_s = -g \frac{e\vec{B}_0}{2m_\mu} - (1 - \gamma_0) \frac{e\vec{B}_0}{\gamma_0 m_\mu} \quad \text{and} \quad \vec{\omega}_c = -\frac{e\vec{B}_0}{\gamma_0 m_\mu}.$$
 (1.19)

In Eq. (1.19), g, e, γ_0 , and m_{μ} are the g-factor, electric charge, ideal Lorentz factor, and mass of the muon, respectively. The adjective magic for the momentum case p_0 denotes the convenient case in which the electric fields used to confine muons in the vertical direction of the muon g-2 storage ring do not directly introduce additional spin precessions in the cyclotron frame (see Eq. (1.30), where the term with the electric field \vec{E} involved vanishes for muons with magic momentum, i.e., $\delta = \Delta p/p_0 = 0$).

For this case, a frequency of the spin relative to the muon's direction of motion, known as the *anomalous precession frequency*, can be well defined:

$$\vec{\omega}_a \equiv \vec{\omega}_s - \vec{\omega}_c = -a_\mu \frac{e\vec{B}_0}{m_\mu}.$$
(1.20)

This direct relation between $\vec{\omega}_a$ and a_{μ} in Eq. (1.20) is the foundation of Fermilab's muon g-2 experiment; a careful measurement of $\vec{\omega}_a$ is tantamount to a precise measurement of the muon's anomalous magnetic moment.

Without any radiative corrections, a_{μ} would be equal to zero, and the relative angle between momentum and spin in the storage ring would not change. However, as this is not the case, the anomalous magnetic moment introduces a frequency of $\omega_a \approx 4.37 \,\mu\text{s}$ (i.e., about one revolution every 29.33 turns around the storage ring).

The anomalous precession frequency is measured by exploiting parity violation in the $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$ weak-decay channel. In the muon's rest frame, a positron with the highest possible energy (i.e., with momentum $p'_{e\ max} \approx 53 \,\text{MeV}/c$) is produced when the two neutrinos are parallel to each other. On the other hand, parity violation in weak decays constraints the spin and momentum directions of the nearly massless emitted neutrino(anti-neutrino) to be anti-aligned(aligned) (i.e., ± 1 helicity). Consequently, conservation of angular momen-

tum implies that the emitted positron fully inherits the muon's intrinsic angular momentum. Therefore, since the weak interaction couples with the right-handed part of the positron, its emission occurs preferentially in the direction of the muon spin. In more general terms, from V-A theory [31], the differential decay distribution of positrons from $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_{\mu}$ in the muon's rest frame (given the positron's energy much larger than its rest mass) is equal to:

$$dP(y',\theta') \propto n'(y') \left[1 + \mathcal{A}(y')\cos\theta' \right] dy' d\Omega'.$$
(1.21)

Here, $d\Omega'$, y', and θ' are the solid angle, fractional momentum of the positron p'_e/p'_e_{max} , and angle between the positron-momentum and muon-spin directions, respectively. The quantities n'(y') and $\mathcal{A}(y')$ are given by:

$$n(y') = 2y'^2(3 - 2y')$$
 and $\mathcal{A}(y') = \frac{2y' - 1}{3 - 2y'}$. (1.22)

Both n'(y') and $\mathcal{A}(y')$ increase for higher y' values, which translates into decay positrons emitted along the muon's spin direction being a more probable process, especially for $y' \ge 0.5$.

In the laboratory frame, a Lorentzian boost of Eq. (1.21) yields a time-dependent number of decay positrons from a muon beam proportional to:

$$N_e(t, E) \propto e^{-t/\gamma \tau} N_{e0}(E) \left[1 + A_e(E) \cos(\omega_a t + \varphi_0(E))\right],$$
 (1.23)

where

$$N_{e0}(E) \propto (y-1)(4y^2 - 5y - 5)$$
, $A_e(E) = \mathcal{P}\frac{-8y^2 + y + 1}{4y^2 - 5y - 5}$, $y = \frac{E}{E_{max}}$, (1.24)

Figure 1.5: Number of positrons from a highly polarized muon beam ($\mathcal{P} = 0.95$) decaying via $\mu^+ \to e^+ \nu_e \bar{\nu}_{\mu}$, subject to the positron energy E in the laboratory frame and ignoring the exponential term $e^{-t/\gamma\tau}$. The energy distribution oscillates as the muon beam polarization rotates relative to the beam's direction of motion with an angular frequency ω_a independent of time. The black curve corresponds to the polarization parallel to momentum, whereas the blue and red curves show the energy distribution when these two directions are perpendicular and anti-parallel to momentum, respectively. Arrows on the top-right corner illustrate polarization directions relative to momentum direction (gray), with the same color scheme as the curves. The oscillation is statistically maximized when integrating above ~ 1.8 GeV.

E is the positron energy in this frame and \mathcal{P} is the muon beam polarization. $\gamma \tau \approx 64.44 \mu s$ is the dilated muon lifetime and $E_{max} \approx 3.1 \,\text{GeV}$ the maximum positron energy in the laboratory frame for magic-momentum muons. Ignoring the exponential term, Fig. 1.5 illustrates the oscillation of $N_e(E)$ for a highly polarized muon beam.

In the experiment, positrons above a threshold energy E_{th} are selected to maximize the statistical power of the detected number-of-positrons signal:

$$N(t, E_{th}) = N_0(E_{th})e^{-t/\gamma\tau} \left[1 + A(E_{th})\cos(\omega_a t + \varphi_0(E_{th}))\right], \qquad (1.25)$$

where

$$N_0(E_{th}) \propto (y_{th} - 1)^2 (-y_{th}^2 + y_{th} + 3) \quad , \quad A(E_{th}) = \mathcal{P} \frac{y_{th}(2y_{th} + 1)}{-y_{th}^2 + y_{th} + 3}, \tag{1.26}$$

and $y_{th} = E_{th}/E_{max}$. When a fitting of the form of Eq. (1.25) is performed to data collected as shown in Fig. 1.6, the threshold energy that minimizes the statistical fractional error, inversely proportional to $\sqrt{NA^2}$ [32], is $E_{th} \approx 1.8$ GeV, where detectors acceptance and energy resolution play a role. Additional effects from detection acceptance must be included in Eq. (1.25) to obtain a reasonable χ^2 -value when fitting collected data for a clean extraction of ω_a [33].

Figure 1.6: Number of positrons above energy threshold detected at Fermilab's muon g-2 experiment, Run-1.

1.2.2 Muon *g*-2 detection systems

A set of 24 calorimeter detectors equidistantly distributed along the inner part of the storage ring has the primary purpose of measuring ω_a . By measuring the energy and arrival time of positrons, calorimeters count the number of positrons over time produced by the muon beam as it decays while circulating the storage ring. This way, the modulated signal as shown in Fig. 1.6 is obtained for the subsequent extraction of the anomalous precession frequency.

Each calorimeter station is composed of $25 \text{ mm} \times 25 \text{ mm} \times 140 \text{ mm}$ crystals made of PbF₂ and arrayed in a 9(wide) : 6(tall) grid [34]. The depth of the crystals (140 mm) equals about 13 radiation lengths, allowing for stopping positrons effectively. The energy deposited by the positrons into the crystal lead-fluoride material excites e^+e^- production, from which short-pulsed Cherenkov light is emitted. The total amount of light bounces toward Silicon PhotoMultipliers (SiPMs), where photons hit electrons in pixels that then cascade into a measurable current (and posteriorly amplified multiple times). The emanated digitized pulses are fitted to get a peak time and pulse integral, proportional to the positron's arrival time and energy, respectively.

In order to fulfill the precision goals of the ω_a measurement, calorimeters have to distinguish light showers separated by 5 ns or more with 100% efficiency and must support a time resolution smaller than 100 ps of the short-pulsed signals. The systematic uncertainty associated with the pileup of two low-energy positrons entering a PbF₂ crystal with similar impact times and being recorded as one signal is reduced with such requirements. Since the timearrival measurement is taken from positrons above a specific energy threshold, an energy resolution of 5% at 2 GeV is sufficient. Furthermore, a laser calibration system guarantees residual gain stability while correcting gain drifts during the measurement time window. In addition to the calorimeter detectors aimed to measure the anomalous precession frequency, the muon g-2 experiment at Fermilab possesses supplementary detection systems to characterize the spatial and temporal distributions of the injected muon beam. On the one hand, the beam profile (together with its intensity and relative arrival time) is measured upstream of the entrance to the storage ring with a SiPM and photomultiplier tubes (PMTs) attached to a scintillator [35]. On the other hand, an inflector beam monitoring system (IBMS) of three scintillating-fiber retractable detectors—placed nearby the hole in the ring's magnet yoke through which the beam enters the ring—provides beam profile measurements in the transverse plane (i.e., 2D space spanned by unit vectors \hat{e}_x and \hat{e}_y , where \hat{e}_x is a horizontal vector perpendicular to the idealized direction of the beam motion \hat{e}_s , and \hat{e}_y points vertically upward such that $\hat{e}_s \times \hat{e}_x = \hat{e}_y$) during beam injection for beam-tuning purposes [36]. Furthermore, a set of two "fiber harp" detectors, each made of seven parallel scintillating fibers, measures the profiles of the beam in both horizontal and vertical directions when inserted into the storage region of the ring [37].

Of particular importance in the context of the work presented in this thesis is the Muon g-2 straw tracking detection system [38]. Its ability to measure the transverse beam profile non-destructively at two azimuthal locations of the ring⁴ allows for a thorough determination of the muon beam dynamics along the entire ring and, moreover, the reconstruction of unmeasured guide fields under special conditions as described in detail in Chap. 3. Its main principle to resolve the transversal coordinates of a muon is to reconstruct its position before decay based on the detected trajectory of the corresponding decay positron.

A straw tracking station consists of eight detector modules in series (see Fig. 1.7), where

 $^{^{4}}$ A third station is probable to be installed in the fiscal year 2021 or afterward for the remaining datataking g-2 runs at Fermilab.

four layers of 32 straws of 5 mm in diameter are grouped in pairs of two and oriented at $\pm 7.5^{\circ}$ away from the vertical to resolve vertical locations. The straws are coated with gold on their inner wall and grounded to act as a cathode, in conjunction with a 25 µm-thick wire made of gold-plated tungsten and placed along the straw axis. A positive high voltage of 1.625 kV is applied across the wires to create a cylindrical electric field. As decay positrons cross the straws, argon gas trapped inside is ionized along their path. The released electrons form an avalanche strongly attracted by the electric field towards the wire in the center, inducing a detectable signal. A quench gas (i.e., ethane) is also added to a 1:1 ratio with the argon gas in the interior of the straws to avoid secondary avalanches originated beyond the positron trajectory, which would add false track signals to the main readouts. Additionally, a small amount of water is confined inside the straws to help reduce their aging. A fitting algorithm extrapolates the momentum and time back to the muon decay position.

Figure 1.7: (a) Straw tracking station and (b) a detector module [38].

Figure 1.8: Muon g-2 storage ring housed at Fermilab. The steel yokes and superconductive coils crossed thousands of miles from Brookhaven National Laboratory to Fermilab for extended use. After the first data-taking period at Fermilab, the storage ring magnet was covered with thermal insulation to reduce temperature gradients that affect the uniformity of the magnetic field.

1.2.3 The muon g-2 magnetic field

In concert with the anomalous precession frequency measurement, the magnetic field utilized at E989 [39] to induce this precession must be known to a precision of 70 ppb or less in order to achieve the experimental goals.

A vertical magnetic field of $p_0/er_0 \approx 1.4513$ T is supplied by four circular superconducting coils operating at about 5200 A [30], exciting the g-2 Storage Ring magnet (See Fig. 1.8) which is built as one continuous superferric magnet made of mainly six layers of high-quality magnet steel and two pole pieces as shown in Fig. 1.9. With the yoke steel manufactured for the muon g-2 experiment at BNL being reused at E989, the physical parameters of the g-2 storage ring magnet are unchanged (see Table 1.2). Nevertheless, the magnetic field shimming at E989 for the first data-taking runs achieved a uniformity of the magnetic field

Figure 1.9: Cross section of the storage ring magnet. The yoke is made of six layers of magnet steel with an open side to allow for positrons from muon decay to reach the inner side of the ring. A total of twelve of these sections assembled together provide a continuous and ultra-uniform magnetic field within the pole's gap, where the stored muon beam revolves for several thousands of turns. Passive and active shimming via surface currents, thousands of pieces and around the muon storage region, and other movable pieces of the storage ring magnet allow to calibrate and further reduce inhomogeneities of the magnetic field in the storage region [40].

improved by a factor of two [41].

A network of pulsed nuclear magnetic resonance probes (pNMR) is used to measure the magnetic field in the muon storage region [40]. An RF magnetic field rotates the net magnetization of protons in petroleum jelly samples inside the pNMR probes by $\pi/2$ rad with respect to the mostly vertical magnetic field from the storage ring. By virtue of the Larmor precession of spins under the influence of an external magnetic field, the magnetization rotates around the storage ring's B-field with a Larmor frequency $\omega_L = geB/2m$ until relaxing back to equilibrium, parallel to the external field. The 'free induction decay' signal

Parameter	Value
Design magnetic field	$1.45\mathrm{T}$
Design current	$5200\mathrm{A}$
Design orbit radius	$7.112\mathrm{m}$
Nominal gap between poles	$18\mathrm{cm}$
Iron mass	$682 \mathrm{tons}$
Magnet self-inductance	$0.48\mathrm{H}$
He-cooled lead resistance	$6\mu\Omega$
Warm lead resistance	$0.1\mathrm{m}\Omega$
Yoke height	$157\mathrm{cm}$
Yoke width	$139\mathrm{cm}$
Pole Width	$56\mathrm{cm}$

Table 1.2: Magnet parameters of the g-2 storage ring.

corresponding to this relaxation is read out by pickup coils embedded inside the pNMR probes. These signals provide a 10 ppb-precision measurement of the Larmor precession frequency, which in turn yields the magnetic field at the location of the material sample within the probe.

A set of 17 pNMR probes distributed across a trolley, as shown in Fig. 1.10, periodically measures the magnetic field in the storage region of the ring. When the Muon Campus at Fermilab is not delivering the beam to the muon g-2 experiment, rails around the storage ring guide the trolley around the storage region to capture local variations of the magnetic field. For the conversion from petroleum jelly to free proton Larmor frequencies and calibration of the trolley probes, a 'plunging' pNMR probe with water as the proton sample is used [42]. Additionally, 378 fixed probes distributed along the ring's azimuth (see Fig. 1.9) are constantly taking data, even during muon beam storage, to interpolate data recorded by the trolley.

Figure 1.10: Array of pNMR probes installed in the trolley (white circles), used to periodically measure the magnetic field in the storage region. Fixed probes installed above and below the storage region (shown in Fig. 1.9) are used to interpolate the magnetic field data between trolley runs. The heat map represents a typical sample of the magnetic field from trolley data fitted with a multipole expansion, within the storage region and averaged azimuthally along the ring [39]. The color legend units are Tesla.

1.3 Beam Dynamics: Requirements

1.3.1 Polarization and beam production performance

It is essential for the muon g-2 experiment to control and minimize the statistical and systematic uncertainties of the anomalous magnetic moment measurement. The need of sufficient number of positrons that compose the data (Fig. 1.6) to deliver a ω_a measurement to a statistical precision of 100 ppb or less sets the statistical minimum limit. In a method with energy thresholds as in Eq. (1.25), such statistical error $\delta \epsilon$ [30] is subject to the beam polarization \mathcal{P} of the injected muon beam via the asymmetry (A in Eq. (1.26)):

$$\delta\epsilon = \frac{\sqrt{2}\omega_a}{\tau_\mu \sqrt{NA^2}}.\tag{1.27}$$

As explained in Sec. 2.3.2, the muon beam production across the Muon Campus at Fermilab exploits parity violation in the $\pi \to \mu \nu_{\mu}$ decay which, constrained by the momentum acceptance, transports longitudinally polarized muons through the beamlines. A highly polarized muon beam is therefore expected to be injected into the storage ring. However, while muons exponentially decay at different locations of the beam delivery system, the coupling between the muon production location and beamline elements distribution along the Muon Campus can potentially affect the resulting beam polarization. These latent imprints on \mathcal{P} and other possible sources of de-polarization are presented in Chap. 2 as well as the beam production performance, to which the stored positrons rate in the storage ring is bounded.

From the systematic-errors front, correlations between beam polarization and other dynamic variables can lead to apparent ω_a shifts, caused by the so-called "g-2 Phase" φ_0 in the functional form "f(t)" used to extract the anomalous precession frequency from data (see Eq. (1.25)):

$$f(t) \propto \cos\left(\omega_a t + \varphi_0\right). \tag{1.28}$$

The g-2 phase represents the overall muon beam angle between spin and momentum at injection time. Besides positron detection effects, stored muons that do not contribute to an expected calorimeter signal—due to them being lost by hitting instrumentation during data collection—can potentially introduce a time-dependent g-2 phase. If the individual phases of these "lost muons" are not equal to each other and, additionally, are correlated with an observable Z, the corresponding apparent ω_a can be quantified:

$$\Delta\omega_a(t) = \frac{d\varphi_0(t)}{dt} = \frac{d\varphi_0}{d\langle Z \rangle} \Big|_{t_0} \frac{d\langle Z(t) \rangle}{dt}.$$
(1.29)

Lost muons favoring specific values of Z yield a nonzero $\Delta \omega_a(t)$ if $d\varphi_0/d\langle Z \rangle \neq 0$. Section 4.2 presents the contribution to this systematic error by taking the momentum of the muons as the observable Z in data-driven simulations of the beam delivery system and storage ring.

1.3.2 Beam characterization along the entire storage ring

The g-2 straw tracker detectors permit to precisely determine several properties of the beam circulating the storage ring (see Sec. 1.2.2). With the broad transverse acceptance at the tracker locations, a small spatial resolution of a few millimeters, and a time resolution of less than 3.4 ns, it is possible to measure the beam widths, centroids, and longitudinal decoherence on a run-by-run basis. Nevertheless, such information is limited to the locations where the two trackers are placed, as shown in Fig. 1.11. For this reason, in order to characterize the beam behavior along the whole azimuthal extension of the ring for quantifying beam-dynamics-related systematic errors, a dedicated model of the storage ring is appropriate for this purpose.

The g-2 storage ring is a rather weakly focusing system on which a mismatched muon beam is injected, occupying most of the 45 mm storage aperture. Moreover, in addition to coherent betatron oscillations due to beam-ring mismatch, the ppm-level inhomogeneities of the vertical magnetic field and sub-mm misalignments of electrode plates used for vertical beam focusing originate millimetric azimuth-dependent distortions of the closed orbit around which the beam revolves the ring. In principle, these features together with $\sim 2\%$ beam width

Figure 1.11: Horizontal (left) and longitudinal (right) acceptances of the two g-2 straw tracker detector stations [43]. Each tracker station reads decay vertexes along azimuthal segments of ≈ 0.4 mrad, whose maximum acceptance peaks are positioned at about 1 m upstream of the modules.

longitudinal variations of hundredths of microns across the ring do not significantly affect the g-2 measurement to first order. However, due to the tight systematic-error budget of the experiment, the aforementioned transverse variations of the stored muon beam need to be accounted for.

In particular, the coupling between the g-2 phase and detection acceptance [44] introduces a phase dependence on time when the beam moments exhibit coherent drifts (especially the vertical beam width, which strongly couples to the calorimeter muon efficiency). During the first official run of the experiment, this was the case as a consequence of damaged instrumentation [45]. A method that takes the beam profile measured by the straw tracker and calorimeter detectors as input and provides a full reconstruction of the time-dependent electric guide fields during the first g-2 run is elaborated in Chap. 4. With the reconstructed fields and the storage ring model explained in Chap. 3, a full characterization of the muon beam is delivered, which is critical to the determination of the aforementioned largest systematic uncertainty for the first g-2 official results.

Another relevant case is the magnetic field that plays a role in the anomalous magnetic moment (see Eq. (1.20)). In E821, it was calculated by averaging a multipole expansion of the magnetic field—azimuthally averaged and from representative NMR trolley runs [8]—with the muon distribution moments. Though this approach does not account for the entanglements between azimuthal variations of the muon distribution and the magnetic field, the associated systematic error is negligible compared to the statistical error from E821 [46]. But for the muon g-2 experiment at Fermilab, the targeted systematic uncertainty of the muon-weighted magnetic field is 10 ppb or less, demanding a different approach. In Chap. 4, a method to calculate the magnetic field experienced by muons at E989 is presented together with related systematic-error studies.

1.3.3 Momentum spread and vertical motion

In terms of the magnetic (\vec{B}) and electric (\vec{E}) guide fields within the storage ring, the anomalous precession frequency ω_a is the precession frequency of the muon beam polarization [47, 48] relative to its momentum in the lab frame, which can be defined for the muon g-2 experiment at Fermilab as:

$$\omega_a = \left| \langle \vec{\omega}_S - \vec{\omega}_C \rangle \right| = \left| -\frac{e}{m_\mu} a_\mu \tilde{B} + \frac{e}{m_\mu} a_\mu \left\langle \left(\frac{\gamma}{\gamma + 1} \right) (\vec{\beta} \cdot \vec{B}) \vec{\beta} + \left(1 - \frac{1}{(1 + \delta)^2} \right) \frac{\vec{\beta} \times \vec{E}}{c} \right\rangle \right|, \tag{1.30}$$

where $\vec{\omega}_S$ and $\vec{\omega}_C$ are the spin and cyclotron frequencies, respectively, γ the Lorentz factor, $\vec{\beta}$ the velocity in speed-of-light units, and δ the momentum offset relative to magic momentum $p_0 = m_{\mu}c/\sqrt{a_{\mu}}$. Under conventional g-2 storage ring settings, ω_a is treated as the first term on the right-hand side of Eq. (1.30) (aka g-2 frequency) with the explicit addition of the socalled "E-field" (C_e) and "pitch" (C_p) corrections, whose standard expressions are derived from Eq. (1.30) [30, 49] (see Fig. 1.12):

$$\omega_a = \omega_{a0} \left(1 + \langle \Delta \omega_a^e / \omega_{a0} \rangle + \langle \Delta \omega_a^p / \omega_{a0} \rangle \right) \approx \omega_{a0} \left(1 - C_e - C_p \right), \tag{1.31}$$

where $\omega_{a0} = -(e/m_{\mu})a_{\mu}\tilde{B}$ and \tilde{B} is the muon-weighted magnetic field [39].⁵ In Eqs. (1.30)

Figure 1.12: Illustrations of the pitch (left) and E-field (right) corrections. The pitch correction emerges mainly from the transverse vertical motion of muons in the lab frame; the standard pitch correction becomes non-negligible at E989 for the typical vertical oscillations maintained by the storage ring (i.e., $\leq 2 \text{ mrad}$ vertical tilt angles relative to the horizontal midplane). In the E-field correction, the spin of muons away from the magic momentum $p_0 = m_{\mu}c/\sqrt{a_{\mu}}$ experiences rotations mostly contained in the transversal plane as expressed in the last term of Eq. (1.30). The momentum acceptance $\delta \sim 0.5\%$ and the electric field, $E_y \sim 6 \text{ kV/cm}$ at 4 cm from the ideal orbit, provided by the Electrostatic Quadrupole stations (ESQ) contribute to an overall vertical precession frequency of about 400 ppb opposite to the nominal g-2 frequency.

and (1.31), the delimiters $\langle \rangle$ denote quantities averaged over the stored muons.

At present, the amount e/m_{μ} in Eq. (1.31) contributes to an uncertainty of about 26 ppb [17], while the magnetic field experienced by muons at E989 is expected to be measured to

⁵Indirect ω_a biasing from the *g*-2 time dependencies due to muon loss " C_{ml} " and phase acceptance " C_{pa} " effects, introduced in this section, can also be added to Eq. (1.31) similar to C_e and C_p .

a precision of 70 ppb or less. On the other hand, the E-field and pitch corrections lower the nominal frequency ω_a by a non-negligible level of the order of tenths of ppm. The standard formulae of these corrections are given by [30,49]

$$C_e = \frac{n_0 \beta_0^2}{1 - n_0} 2\left<\delta^2\right> \tag{1.32}$$

and

$$C_p = \frac{n_0}{2\rho_0^2} \left\langle y^2 \right\rangle, \tag{1.33}$$

where the subscript 0 denotes the nominal case of a muon with magic momentum and no betatron amplitudes. The field index $n_0 = -(39/90)(\rho_0/vB_y)\partial E_y/\partial y$ is the effective field index commonly used in the muon g-2 collaboration [50], which is proportional to the nominal orbital radius $\rho_0 \approx 7.112$ m and the axial focusing gradient $\partial E_y/\partial y$. Figures 1.13 and 1.14 illustrate typical relative-momentum and vertical beam spreads, which yield corrections in the order of $C_E \rightarrow \mathcal{O}(400 \text{ ppb})$ and $C_p \rightarrow \mathcal{O}(200 \text{ ppb})$. However, several assumptions are

Figure 1.13: Sample of the muon spread distribution from Fast Rotation analysis [45].

needed to be imposed in order to get the standard equations (1.32) and (1.33), including

Figure 1.14: Vertical beam profile from the tracking detection system [45].

- continuous electrostatic quadrupole stations (and thus no fringe fields),
- linear guide fields,
- harmonic transverse motion, and
- orbital muon frequencies beyond the ballpark g-2 frequency.

For the purpose of validating the standard E-field/pitch corrections and assessing any associated systematic errors, direct calculations of ω_a were carried out via nonlinear orbital and spin tracking (see Chap. 4). Several of the assumptions to derive C_e and C_p were also tested with simulated storage ring configurations.

Another effect from the beam dynamics front that introduces a considerable systematic correction to C_e is the momentum-time correlation [51]. By construction, the overall momentum spread in Eq. (1.32) is obtained from the Fourier transform of the intensity signal

(see Fig. 1.15) detected by calorimeters. When the relative time-of-flight and momentum

Figure 1.15: Beam transverse intensity from realistic storage ring simulations, referred as the fast-rotation signal. Due to momentum spread, the range of cyclotron frequencies causes high- and low-momentum muons to recombine as the beam decoheres in the longitudinal direction. The cyclotron frequencies distribution is recovered from a Fourier transform, which yield the momentum spread distribution (see sample in Fig. 1.13) for the E-field correction.

coordinates of the muon beam are uncorrelated at the start time of the Fourier analysis, all the cyclotron frequencies are equally weighted in the transformation as expected. Alas, a momentum-time correlation breaks the symmetry, which potentially distorts the momentum spread reconstruction for C_e . Correlations between momentum and times-of-flight in the stored beam are a consequence of an imperfect injection kicker; the under-kicking of high-momentum muons out of sync with the kicker-strength peaks favors them to end up getting stored. The ringing of the kicking signal also dictates which muons are stored. With a detailed modeling of the Run-1 injection kicker as well as beam collimation and realistic parameters of the storage ring, the momentum-time distribution—unmeasured at the time of this dissertation—is calculated (Sec. 3.5.4) and allows for C_e systematic correction quantifications.

Chapter 2

The Beam Delivery System (BDS)

2.1 Introduction

The number of recorded high-energy positrons from muon decay in the g-2 storage ring at E989 is required to increase by a factor of 20 with respect to E821. The Fermilab Muon Campus E989 beam delivery system (BDS), which is a series of 1 km long beamlines between the pion production target and the entrance of the Muon g-2 Storage Ring (SR), is designed to meet the statistical goal and deliver $(0.5-1.0) \times 10^5$ highly polarized muons to the storage ring per 10^{12} protons that arrive at the pion production target.

On the other hand, the relative statistical uncertainty in the experimental a_{μ} is inversely proportional to the muon beam polarization (see Eq. (16.6) in [30]). Thus, it is worth studying the effect of nonlinearities and performing spin dynamics simulations. In addition, due to the momentum acceptance (i.e., relative momentum range that a machine can sustain) of about $\pm 0.5\%$ in the storage ring, it is of interest to numerically evaluate the dynamical properties of the muon beam as it is delivered to the storage ring.

Motivated by these reasons, a model of the E989 beamlines [52] was developed to reproduce numerical simulations of the muon beam's statistical performance and dynamical behavior, including spin using COSY INFINITY [53, 54]. In particular, the transport efficiency of secondary protons, pions, daughter muons from pion decay, and muons produced right at the entrance of the E989 beamlines downstream of the pion production target is addressed in these high-statistical simulations. Nonlinear effects due to standard fringe fields, up to fourth-order beam dynamics, spin dynamics, beam collimation, and misalignments of the multiple BDS beamline elements are examined.

This chapter begins with a description of the Muon Campus E989 beam delivery system. Then, details of the beam dynamics simulations throughout the E989 beamlines from the production target to the storage ring entrance and beam performance results modeling nonlinear effects are described.

2.2 The E989 Beam Delivery System (BDS)

The main purpose of the E989 beamlines analyzed in simulations, depicted in Fig. 2.1, is to deliver a clean muon beam with "magic momentum" $p_0 \sim 3.094 \,\text{GeV}/c$ (see Sec. 1.2.1) to the storage ring. Batches of four bunches made of 10^{12} protons each are directed to an Inconel-600 "pion production" target—an alloy of iron, chromium, and nickel—located at the AP0 target hall (a long-existing building of the accelerator complex at Fermilab), from which positive secondary particles emerge. The main components and beamline sections of the Fermilab Muon Campus E989 beam delivery system (BDS) are the aforementioned target station, the M2/M3 beamlines, the Delivery Ring, and the M4/M5 beamlines, described next.

2.2.1 The pion production target station

The Pre-Accelerator, Linac, Booster, MI-8 line, and Recycler as part of the Fermilab Accelerator Complex deliver $8.9 \,\text{GeV}/c$ protons to the Pion production target station, which

Figure 2.1: A schematic layout of the beam delivery system (BDS). Secondary particles (mostly pions, muons, and protons) downstream of the target station at AP0 are canalized through the M2/M3 lines and injected into the Delivery Ring (DR), where protons are discarded and most of the remaining pions decay after four turns. A cleaner beam of mostly muons is extracted to the M4/M5 lines and ultimately delivered to the Muon g-2 Storage Ring (SR).

is the already existing target station that was in operation for antiproton production prior to the Tevatron Collider shutdown but repurposed for pion production. Figure 2.2 illustrates the proton pulses per cycle. A magnetic quadrupole triplet focuses the proton pulses

Figure 2.2: Time structure of the 10^{12} -, 120 ns-pulse train impinging the production target per cycle [55].

upstream of the production target to a transverse size of about $150 \,\mu\text{m}$ to minimize beam loss [56]. 30 cm downstream of the Inconel 600 production target, a 160-kA current flowing through a lithium cylinder provides a 232 T/m strong magnetic gradient around the optical axis (i.e., the ideal trajectory of the beam around which beamline elements are positioned) to transversely focus the secondary particles that emerge from the target. Thereafter, a pulsed magnet called "PMAG" with a field of 0.53 T selects $3.115 \text{ GeV/}c \pm 10\%$ positive particles and bends them 3° up, towards the 50 m long M2 line.

2.2.2 M2/M3 beamlines

Encompassing a total of 50 m of beamlines, starting from the lithium lens and leading to the intersection with the M3 line further downstream, the M2 beamline collects the pions separated by the PMAG and is designed to transport magic-momentum muons with momentum and transverse acceptance¹ of $\pm 2\%$ and 40 mm.mrad, respectively, from pion decay. The M3 beamline, a ~ 230 m section of mainly focusing/defocusing quadrupole magnets and bending insertions, shares the same goal as the M2 line in order to deliver a beam composed of mostly pions, muons, protons that bypass the production target, and other secondary particles to the Delivery Ring. The optical lattice of the M2/M3 beamlines is shown in Fig. 2.3, which, together with the beamline apertures and post-target beam conditions, dictate the number of particles that enter the Delivery Ring (see Fig. 2.4).

To assess the transport performance of the beam throughout the beamlines, Courant-Snyder α , β , and γ parameters are commonly used [58]. Of particular interest are the β and η functions which characterize the beam transverse² width and dispersion,³ respectively

¹Similar in concept to the momentum acceptance previously defined, the transverse acceptance (or admittance) is the maximum sustainable area of a particle beam in transverse phase space (spot size and divergence) within the limiting apertures of a beamline.

 $^{^{2}}$ The word *transverse* denotes the direction perpendicular to the main direction of the beam motion, parallel on average to the so-called optical axis.

³The letter D is also used to symbolize the dispersion function.

Figure 2.3: M2/M3 beta and dispersion functions. The horizontal dispersion (solid green line) originated by the pulsed magnet at the start of the M2 line is canceled out by a switch dipole 50 m downstream, whose large pole width accommodates the beam to enter the M3 line. At around 170 m, the 100 m FODO channel (i.e., an alternating-gradient arrangement of magnetic quadrupoles focusing(defocusing) and defocusing(focusing) in the horizontal(vertical) direction) is interrupted by two horizontal bends (18.3 °) to align the optical axis with the downstream beamline and a quadrupole triplet to cancel out horizontal dispersion. On the right-hand side of the plot, the optical functions reflect the geometric and optical matching section to transport the beam to the Delivery Ring, elevated approximately 4 ft above from the M3 line.

(for more details, see Eqs. (3.53) and (3.57)). These functions are calculated with COSY INFINITY [53] by transporting the initial values α_0 , β_0 , and γ_0 —which are calculated from the beam spot size and divergence at 0.723 m upstream of the PMAG—in the horizontal direction x, as follows from the explicit transformation of the invariant ellipse defined by the Courant-Snyder parameters [59, 60]:

$$\begin{pmatrix} \beta_x(s) \\ \alpha_x(s) \\ \gamma_x(s) \end{pmatrix} = \begin{pmatrix} (x|x)^2 & -2(x|x)(x|a) & (x|a)^2 \\ -(x|x)(a|x) & (x|x)(a|a) + (a|x)(x|a) & -(x|a)(a|a) \\ (a|x)^2 & -2(a|x)(a|a) & (a|a)^2 \end{pmatrix} \begin{pmatrix} \beta_{x0} \\ \alpha_{x0} \\ \gamma_{x0} \end{pmatrix}.$$
(2.1)

The vertical Courant-Snyder parameters (denoted with subscript y) are transformed in

Figure 2.4: Number of muons, μ^+ , pions, π^+ , and protons, p^+ , per proton on target (POT) along the M2/M3 beamlines. The horizontal axis represents the longitudinal distance of the optical axis. Main muon losses of about 11% and 20% take place at the 18.5° horizontal bend $(s \sim 160.0 \text{ m})$ and along the vertical injection upstream of the DR ($s \sim 280.0 \text{ m}$), respectively. The star-shaped marker around $s \sim 235 \text{ m}$ depicts the number of total particles per POT from measurements (Fig. 3 in [57]).

a similar way as in Eq. (2.1), where the variable s denotes the longitudinal distance along the optical axis relative to the coordinates of the initial Courant-Snyder parameters. The elements inside the transformation matrix are linear components of the transfer map (see Eqs. (2.2) and (2.3)), calculated from the beamline settings during Run-1 of the muon g-2 experiment as

$$\begin{pmatrix} x(s_2) \\ a(s_2) \\ \delta \end{pmatrix} = \begin{pmatrix} (x|x) & (x|a) & (x|\delta) \\ (a|x) & (a|a) & (a|\delta) \\ 0 & 0 & (\delta|\delta) \end{pmatrix} \begin{pmatrix} x(s_1) \\ a(s_1) \\ \delta \end{pmatrix},$$
(2.2)

$$\begin{pmatrix} y(s_2) \\ b(s_2) \\ \delta \end{pmatrix} = \begin{pmatrix} (y|y) & (y|b) & (y|\delta) \\ (b|y) & (b|b) & (b|\delta) \\ 0 & 0 & (\delta|\delta) \end{pmatrix} \begin{pmatrix} y(s_1) \\ b(s_1) \\ \delta \end{pmatrix}.$$
 (2.3)

In Eqs. (2.2) and (2.3) and throughout this document, x and y are the horizontal and vertical positions relative to the optical axis, $a = p_x/p_0$ and $b = p_y/p_0$, where p_0 is the reference momentum (in this case the magic momentum) and p_x , p_y correspond to the momentum perpendicular to the optical axis. The variable $\delta = \Delta p/p_0$ symbolizes the momentum offset. Due to the absence of electrostatic fields along the BDS, δ is a constant of motion. On the other hand, the correspondence between dispersion functions and linear matrix components is as follows:

$$\eta_x = (x|\delta) \quad , \quad \eta_y = (y|\delta). \tag{2.4}$$

2.2.3 The Delivery Ring (DR)

At the end of the M3 line, a series of magnets involving a C-magnet, a pulsed magnetic septum dipole, and kicker modules, inject the beam to the Delivery Ring (DR) after a vertically upward bend of about 5.7°. Through the 505 m of circumference of the DR, previously used as a debuncher ring and now reconditioned for the muon g-2 experiment, the remaining pions have enough time to decay into mostly muons as they circulate four times before being extracted into the M4 line (see Fig. 2.5). The DR also allows protons to longitudinally separate from the other lighter particles by a rate of 75 ns per turn [56]; this feature lets a 180 ns rise-time kicker within the DR to safely remove the protons after the fourth turn. The optical functions β_x , β_y , η_x , and η_y of the DR using COSY INFINITY are shown in Fig. 2.6. An arrangement of FODO cells fills all the sections of the DR, interrupted

Figure 2.5: Number of muons, μ^+ , pions, π^+ , and protons, p^+ , per proton on target (POT) along four turns around the Delivery Ring. The design momentum acceptance of 2% reveals naturally in beam tracking simulations when accounting for the beamline apertures present in the DR. All pions decay prior to the third turn along the DR.

Figure 2.6: Beta and dispersion functions at one three-fold symmetric section of the delivery ring (DR) where the longitudinal distance of the beamline is shown in the horizontal axis. Fringe fields modeled in simulations change the beta functions, β_x and β_y , by less than 3%.

by a series of 22 rectangular magnets at each of the three-fold symmetric sections from which horizontal dispersion and spin-momentum beam correlations are originated. The betatron tunes in the DR are approximately equal to 9.78 in both horizontal and vertical directions, whereas the associated chromaticity of the DR sections is balanced by sextupole magnets.

2.2.4 M4/M5 beamlines

After four turns around the Delivery Ring, a system of two kicker magnets at a bending-free section of the DR and parallel to the M3-line end extracts the beam radially outwards into the M4 beamline. The beam is further bent upwards with a set of three vertical bending magnets to reach a final elevation of 0.81 m with respect to the Delivery Ring. 30 m downstream, a beam composed of mostly $|\delta| < 2\%$ muons (see Fig. 2.8) crosses the last 100 m of the BDS, i.e., the M5 beamline. Around $s \sim 70$ m in Fig. 2.7, the radial dispersion introduced by horizontal bending magnets (27.1° deflection) to align the beam towards the muon g-2 storage ring entrance is shown. At the end of the M5 beamline, four tunable sections with four quadrupole magnets provide the appropriate configuration to maximize the stored beam fraction [61].

Figure 2.7: M4/M5 lattice functions calculated with COSY INFINITY. The design of the M4/M5 beamlines favors losses minimization.

Figure 2.8: Number of muons, μ^+ , per proton on target (POT) along the M4/M5 beamlines. The pale-rose dashed line depicts muons within the muon g-2 storage ring momentum acceptance. For g-2 runs posterior to Run-1, the insertion of passive wedge absorbers in the BDS maximized the muon population within $|\delta| < 0.5\%$ to increase the stored beam fraction [62].

2.3 Realistic Modeling of the BDS

With a package dedicated to the design and analysis of particle optical systems as part of COSY INFINITY [53], high-order transfer maps \mathcal{M} calculated with Differential-Algebraic (DA) methods to compute the flow of the beam optics Ordinary Differential Equations (ODEs) are prepared to recreate the beam dynamics along the BDS. By defining the secondary particles beam downstream of the pion production target as an array of scaled coordinates

$$\vec{z} = (x, a, y, b, l, \vec{\delta}), \tag{2.5}$$
BDS beam tracking simulations are performed via

$$\vec{z_f} = \mathcal{M}(\vec{z_0}). \tag{2.6}$$

In Eq. (2.6), the transfer map can represent a single beamline element (e.g., a "quadrupole magnet" with magnetic potential $V_B \propto x^l y^m$ where $\{l, m\} = \{0, 1, 2\}$ and l+m = 2 for beam focusing/defocusing, a "bending magnet" with uniform magnetic field for beam steering, a "magnetic sextupole" for the control of chromatic aberrations [59], or "drifts" with no guiding fields present), a segment, or a set of beamline elements of the BDS, which transforms the vector \vec{z} from the longitudinal position s_0 to s_f . In Eq. (2.5), $l = -(t-t_0)v_0\gamma_0/(1+\gamma_0)$.⁴ For BDS beam tracking simulations using COSY INFINITY, the vector $\vec{\delta}$ contains the kinetic energy and rest-mass offsets (δ_K and δ_m , respectively) relative to the magic-momentum muon.

Tracking simulations of the E989 beamlines start with an initial distribution at the exit of the pion production target from a MARS [63] simulation of 10⁹ protons on target [64]. Protons, positive pions, and positive muons from the target and pion decay (see 2.3.2) are tracked down and collimated by the BDS beamline physical apertures (see 2.3.1). Simulations of the BDS were carried out in parallel computing on clusters from the Department of Physics and Astronomy at Michigan State University.

⁴The subindex "0" corresponds to a reference ray with $\vec{z} = \vec{0}$, lab-frame speed v_0 , time-of-flight t_0 , and Lorentz factor γ_0 .

Table 2.1: Second-order transfer map of the Delivery Ring. The first five columns correspond to $(x|, (a|, (y|, (b|, and (l|, whereas the last column indicates <math>(j_1, j_2, \ldots, j_7)$ in that order. For instance, in the ninth row, first column, the (x|xa) coefficient is displayed.

2.3.1 Beamline elements

The transfer maps \mathcal{M} contain the Taylor coefficients to track each of the z_i components of a ray \vec{z} as follows:

$$z_{i,f} = \sum_{j_1} \cdots \sum_{j_7} (z_i \mid x^{j_1} a^{j_2} y^{j_3} b^{j_4} l^{j_5} \delta_K^{j_6} \delta_m^{j_7}) x_0^{j_1} a_0^{j_2} y_0^{j_3} b_0^{j_4} l_0^{j_5} \delta_K^{j_6} \delta_m^{j_7}.$$
(2.7)

The summations go from $j_i = 0$ up to the chosen map order. As an example, Table 2.1 displays the Delivery Ring transfer map (without fringe fields accounted for).

To assess the statistical performance of the beam across the BDS, transfer maps representing $\sim 20 \text{ cm}$ segments of beamline elements are prepared. In between these sections, specific routines eliminate particles with spatial coordinates beyond the transverse apertures of the BDS beamline elements. Beamline apertures of the BDS take multiple shapes, e.g., circular, rectangular, elliptical, and more involved geometries to accommodate the large transverse acceptance for the muon g-2 experiment, as those present in most of the BDS quadrupole magnets.

2.3.2 Muon production from pion decay

COSY-based modules were implemented in the BDS tracking simulations to account for the following particle decays:

$$\mu^+ \to e^+ + \nu_e + \bar{\nu}_{\mu} \quad , \quad \pi^+ \to \mu^+ + \nu_{\mu}.$$
 (2.8)

Even though the former case (muon decay) is the main channel through which ω_a is experimentally measured in the muon g-2 storage ring, its impact on the beam performance along the BDS is minimal; due to the relatively long muon lifetime in the moving frame, $\gamma_0 \tau_\mu \approx 64.5 \,\mu\text{s}$, compared to the longitudinal extent of the BDS (about 2.4 km when the beam circulates the DR four times), most of the muons emitted near the production target reach the end of M5 unless they hit a beamline element. Furthermore, injected positrons do not survive for more than 4 µs inside the muon g-2 storage ring [65]; thus, positrons are neglected in the studies presented here.

On the other hand, the $\pi^+ \to \mu^+ \nu_{\mu}$ decay requires more attention as most of the muon beam emerges via this channel, and its kinematics dictates the muon beam polarization [66]. Parity violation of the $\pi^+ \to \mu^+ \nu_{\mu}$ weak decay constraints the spin and momentum directions in the pion rest frame of the emitted neutrino to be anti-aligned (i.e., -1 helicity). Therefore, conservation of angular momentum implies that the emitted muon is completely polarized in the pion rest frame.

From two-body kinematics, the constant decay-muon momentum p_{μ}^* and energy E_{μ}^* in the pion rest frame are well defined (c = 1):

$$p_{\mu}^{*} = \frac{(m_{\pi}^{2} - m_{\mu}^{2})}{2m_{\pi}} \quad , \quad E_{\mu}^{*} = \frac{(m_{\pi}^{2} + m_{\mu}^{2})}{2m_{\pi}}$$
(2.9)

where m_{π} and m_{μ} are the pion and muon rest masses, respectively.⁵ In the laboratory frame where the longitudinal axis is parallel to the pion's momentum prior to decay, a Lorentz transformation yields the longitudinal p_L and transverse p_T components of the muon momentum in this frame as follows:

$$p_L = \gamma_\pi (\beta E^*_\mu + p^* \cos \theta^*) \quad , \quad p_T = p^* \sin \theta^* \tag{2.10}$$

where θ^* is a random number, γ_{π} corresponds to the pion's Lorentz factor and $\beta_{\pi} = v_{\pi}/c$ in the lab frame (v is the speed as observed in the lab frame). To express the decaymuon direction in terms of a and b for numerical simulations (see Eq. (2.7)), p_T is randomly decomposed into two orthogonal directions and, together with p_L , transformed to the optical axis frame:

$$a_{\mu} = \frac{1}{p_0} \left[f \left(p_L \sqrt{1 - \left(\frac{b_{\pi}}{1 + \delta_{\pi}}\right)^2} - p_T \cos \alpha \frac{b_{\pi}}{1 + \delta_{\pi}} \right) + p_T \sin \alpha \sqrt{1 - f^2} \right]$$
(2.11)

 $^{^5\}mathrm{The}$ neutrino mass has been approximated to zero

Figure 2.9: Momentum spread of the muon beam after four turns around the Delivery Ring. The momentum acceptance sustained at the BDS beamlines allows for the preparation of a highly polarized muon beam (P=0.969 from BDS simulations).

$$b_{\mu} = \frac{1}{p_0} \left[p_L \frac{b_{\pi}}{1 + \delta_{\pi}} + p_T \cos \alpha \sqrt{1 - \left(\frac{b_{\pi}}{1 + \delta_{\pi}}\right)^2} \right]$$
(2.12)

In Eqs. (2.11) and (2.12), α is a uniformly random angle and the subindex " π " denotes z_i coordinates of the pion in the optical frame. The factor f is equal to

$$f = \frac{b_{\pi}}{\sqrt{(1+\delta_{\pi})^2 - b_{\pi}^2}}.$$
(2.13)

The new muon's momentum offset δ_{μ} is axiomatically defined from Eqs. (2.10):

$$\delta_{\mu} = \sqrt{p_L^2 + p_T^2} / p_0 - 1. \tag{2.14}$$

From the muon polarization side, the transverse component of the velocity four-vector is invariant under Lorentz transformation. Consequently, in the optical coordinates the muon polarization is given by

$$S_x = S_L a_\mu - S_T \cos\left(\alpha\right) a_\mu b_\mu + S_T \sin\left(\alpha\right) \tag{2.15}$$

$$S_y = S_L b_\mu + S_T \cos\left(\alpha\right) \tag{2.16}$$

$$S_z = S_L - S_T \cos\left(\alpha\right) b_\mu - S_T \sin\left(\alpha\right) a_\mu, \qquad (2.17)$$

where

$$S_T = \frac{p_\pi m_\mu}{p_\mu m_\pi} \sin \theta^* \quad , \quad S_L = \sqrt{1 - S_T^2}$$
 (2.18)

are the transversal, S_T , and longitudinal, S_L , muon polarizations relative to the pion's motion in the lab frame. From Eq. (2.10) and on the other hand the limited momentum acceptance throughout the Muon Campus (see Fig. 2.9), only decay muons with angles θ^* in the rest frame close to zero—i.e., forward muons—remain within the beamline channel, which further constraints the transversal muon beam polarization S_T yielding a highly polarized muon beam at the end of the M5 beamline as shown in Fig. 2.10.

2.3.3 Nonlinear effects on beam performance

In addition to the linear description of the beam dynamics, COSY INFINITY allows the computation of high-order effects of the beamline elements [54]. Specifically, particle coordinates are calculated as shown in Eq. (2.7). BDS tracking simulations were performed up to fourth-order terms. High-order effects on the beam population were studied with the BDS model by computing the beam performance with and without high-order terms. In

Figure 2.10: Histograms of the normalized muon beam spin components (in natural units) in optical coordinates at the end of M3 (left), Delivery Ring (center), and M5 (right) beamline sections. The polarization projections P_x , P_y , and P_z (parallel to the x, y, and s directions, respectively) are shown inside the thick black frames. As indicated by the projection $P_y = 0$, the high polarization P of the beam is largely contained in the horizontal plane.

Table 2.2, the relative number of particles per species from the production target at the end

of the M3, Delivery Ring, and M5 beamlines is shown.

Table 2.2: Number of protons (p), muons (μ) , and pions (π) along the BDS (quantities per proton on target).

	M3 exit	DR exit	SR entrance
μ 's	2.19×10^{-6}	1.04×10^{-6}	7.48×10^{-7}
μ 's ($ \delta < 0.5\%$)	2.72×10^{-7}	2.85×10^{-7}	1.89×10^{-7}
π 's	1.55×10^{-5}	0	0
$p's^*$	1.24×10^{-4}	6.80×10^{-5}	5.86×10^{-5}

*Results for the case of proton removal at DR turned off.

Figure 2.11 shows the subtle effects of high-order terms (up to fourth) on the muon population as well as pions as they decay. Such nonlinearities tend to reduce the number of muons/pions as they are transported throughout the BDS; nevertheless, the repeated beam collimation, especially across bending elements, washes out the mitigation. Even though the combination of beamlines can accommodate at least 40π mm-mrad phase space, high-order effects do not have a considerable effect on the muon beam population (see Table 2.4).

Figure 2.11: Simulation results of the number of pions and muons with $|\delta| < 2\%$ per POT under up to fourth-order (o4) effects along the M2/M3 lines with fringe fields (FR) turned on. The longitudinal distance along the M2/M3 lines is shown in the horizontal axis. As depicted by the overlapping curves of the muon population for the two o1/o4 cases, linear simulations do not significantly differ from results when high-order terms in the computation of the particle dynamics are simulated.

Map computations of the fields at the longitudinal edges, also known as *fringe fields*, of each beamline element are performed for the analysis of their impact on the beam performance. The longitudinal-dependent tapering of the multipole strengths is modeled by a six parameter Enge function (see Fig. 2.12):

$$F(z) = \frac{1}{1 + \exp\left(a_1 + a_2 \cdot (z/D) + \dots + a_6 \cdot (z/D)^5\right)}$$
(2.19)

where z is the distance perpendicular to the effective field boundary and D is the full aperture of the particle optical element. The a_i coefficients are taken by default based on measured data from PEP at SLAC [54]; for such cases, the integrated multipole strengths along the optical axis of each beamline element remain the same as for simulations with hard-edge modeling, guaranteeing this way reliability in the following comparisons between numerical results with fringe field effects turned on and off.

Figure 2.12: Enge function falloff of a typical dipole element in COSY INFINITY, used to represent fringe fields in the BDS simulations. The aperture for this case is equal to 10 cm.

Fourth-order numerical calculations with and without fringe fields were implemented. Figure 2.13 shows the differences between the two scenarios along the DR. After four turns in the DR, simulations suggest a favorable contribution due to fringe fields on the muons (i.e., 9.4% increase) and pion population. Downstream of the DR, simulation results show an increase of 5.2% more muons at the entrance of the storage ring. Furthermore, fringe fields have a larger contribution in the number of surviving muons than in pions; i.e., at the end of the M3 line (s = 290 m)—where most of the pions still have not decayed—fringe fields maintained 8.9% more muons on track whereas pion population at that location increased by only 0.4%, which is within the $\sim 2\%$ range of the simulations statistical error. Fringe fields do not distort the Courant-Snyder parameters significantly, reflected in the modulated distortion in beta functions which from calculations does not exceed 4% [67].

Figure 2.13: Fringe field effects on the population of pions and muons along the delivery ring (DR). The horizontal axis represents the longitudinal distance corresponding to four consecutive turns in the DR. From the COSY-based BDS model simulations, fringe fields (FR) contribute to maintaining more pions within the apertures of the DR, which consequently increase the population of muons by 9.4% before being extracted to the M4 line. The "o4" abbreviation in the legend denotes the order of the computation (i.e., fourth order).

Misalignments also studied in our COSY-based BDS simulations are introduced by transforming the transport maps that represent each beamline element. Transformations follow randomly Gaussian-distributed horizontal and vertical misplacements with standard deviations of 0.25 mm, introducing constant terms to the maps. A total of ten random misalignment configurations of the beam delivery system initialized with different random seeds were analyzed to obtain statistical ranges within which the beam performance would be expected to occupy.

Figure 2.14 shows how the repercussions of misalignments under consideration could accumulate as muons travel along the BDS, decreasing the number of muons that make it to the end of M5. However, even though the overall misplacements of the beamline elements are Table 2.3: Relative difference in pion population at the end of the M3 beamline from fringe field effects, up to fourth-order nonlinear terms, and random misalignments of beamline elements (horizontal and vertical misplacements with standard deviations of 0.25 mm). Statistical errors in the last row are calculated based on numerical simulations with ten different misplacement scenarios, initialized with independent random seeds.

	M3 exit
Fringe Fields	0.4%
Higher order	-9.6%
Misalignments	$-10.5 \pm 5.5\%$

small, the correctors along the beamlines are expected to mitigate such detrimental effect.

Tables 2.3 and 2.4 summarize the impact of high-order terms, fringe fields, and realistic misalignments on the muon and pion population.

Table 2.4: Relative difference in muon population at the end of the M3, Delivery Ring (after four turns), and M5 beamline sections from fringe field effects, up to fourth-order nonlinear terms, and random misalignments of beamline elements (horizontal and vertical misplacements with standard deviations of 0.25 mm). Statistical errors in the last row are calculated based on numerical simulations with ten different misplacement scenarios, initialized with independent random seeds.

	M3 exit	DR exit	SR entrance
Fringe Fields	8.9%	9.4%	5.2%
Up to fourth order	-1.9%	-2.2%	-1.7%
Misalignments	$-9.2 \pm 9.7\%$	$-27.5 \pm 16.2\%$	$-26.0 \pm 11.6\%$

2.3.4 Spin-orbit correlations

Fringe fields from the BDS beamline elements were also modeled in spin tracking simulations. For the pion decay channel, the resulting muon beam polarization is calculated based on the module explained in Sec. 2.3.2, thereafter tracked with COSY INFINITY's DA mapping methods.

The resulting polarization, shown in Fig. 2.10, is P = 0.97, in agreement with G4BEAMLINE numerical simulations [56] which do not include fringe fields. Therefore, fringe fields do not

Figure 2.14: Simulation results of the muon population with $|\delta| < 2\%$ under the effects of beamline misalignments along the M4/M5 lines. The number of muons per proton on target (POT) is shown in the vertical axis as a function of the longitudinal distance along the M4/M5 lines. The red line depicts the number of muons for the ideal case of no misalignments present in the beam delivery system. The green band summarizes simulation results for several scenarios of beamline elements randomly misaligned in both vertical and horizontal directions.

interfere with the muon beam polarization. Another spin variable worth analyzing is the angle between the spin vector projection in the horizontal plane and the reference optical axis, φ_a , which resembles the phase that is indirectly measured in the storage ring (see Fig. 2.15). The muon beam average precession frequency of this phase, ω_a , plays an essential role in the final measurement of a_{μ} at E989, which implies a deep understanding of its evolution as the beam circulates through the storage ring. In particular, the correlation between φ_a and the Lorentz factor γ of a muon might result in a sub-ppm systematic effect of ω_a . High-momentum muons decay at a slower rate than low-momentum muons and, depending on correlations between φ_a and γ , the overall precession ω_a could shift as the muon beam decays [68].

Figure 2.15: Histogram of the muon spin projection angle in the horizontal plane with respect to the reference optical axis at the storage ring (SR) entrance from simulations. The beam delivery system (BDS) is designed to favor the capture of longitudinally polarized muons from pion decay. However, as the muon beam travels through the bending sections of the BDS—especially along the Delivery Ring which houses multiple rectangular bending magnets—the polarization develops a transversal component before the beam is delivered to the g-2 storage ring.

Tracking simulations were performed with and without fringe fields to study the effect of fringe fields on the spin-momentum correlation $m_{\gamma} = d\langle \varphi_a \rangle/d\gamma$. For the case of fringe fields turned on, simulations show a correlation m_{γ} equal to 29.2 ± 9.4 mrad after four turns around the Delivery Ring as shown in Fig. 2.16. On the other hand, similar simulations without fringe fields (conventional hard-edge model) indicate a correlation $m_{\gamma} = 92.1 \pm 9.8$ mrad. This unexpected discrepancy on spin-momentum correlations apparently originated from fringe field effects of the numerous magnetic beamline elements within the DR, especially the rectangular bending magnets, is worthy of more detailed studies. Specifically, the large error bars in Fig. 2.16 can be reduced by increasing the statistics in simulations. Moreover, higher computational orders of the fields that represent the beamline elements in the BDS

Figure 2.16: Beam average of the spin projection angle in the horizontal plane with respect to the reference optical axis, $\langle \varphi_a \rangle$, versus the Lorentz factor, γ , at the exit of the delivery ring after four turns. Simulation results presented in this figure correspond to our COSY-based BDS model with fringe fields turned on.

COSY-based ring model could be implemented; in this way, the modeling of fringe fields would encompass higher nonlinear effects.

2.4 Conclusions

A detailed model of the beam delivery system at E989 has been developed. Realistic features based on DA methods such as fringe fields, high-order effects, and misalignments are included to describe the statistical and dynamical performance of the secondary beam produced at the pion production target. Simulation results suggest that fringe fields increase the number of muons that are delivered to the storage ring by $\sim 5\%$, whereas the muon beam polarization is unaffected. However, spin-momentum correlations that could add systematic effects to the final measurement of E989 due to differential decays are significantly affected by the fringe fields from the rectangular dipole magnets of the delivery ring; further studies with higher statistics and computational orders in simulations are necessary to confirm this effect. Regarding high-order effects, our numerical studies indicate that they do not affect the secondary beam performance along the BDS. In addition to the presented results, the COSYbased model served to validate numerical calculations prepared by other members of the muon g-2 collaboration and check the performance of the Fermilab Muon Campus E989 beam delivery system.

Chapter 3

Beam Dynamics at the Muon g-2Storage Ring

3.1 Introduction

With a high-fidelity characterization of the muon beam that gets stored inside the g-2 storage ring, the ω_a corrections driven by beam dynamics effects and the magnetic field experienced by the stored beam can be assessed to the precision demanded by the experiment goals. To first order, the periodic functions of the storage ring (i.e., α , β , and γ) together with closed orbit distortions are used to describe the entire azimuthal behavior of the storage ring, beyond the tracker detectors longitudinal acceptance. To higher orders, nonlinear contributions of the storage ring guide fields drive betatron resonances, longitudinal beam de-coherence, amplitude- and momentum-tune shifts, and betatron-amplitude modulations. Furthermore, sensible modeling of the electric and magnetic fields in the ring storage volume allows quantifying the periodic ring functions, as well as the nonlinear effects aforementioned.

For this characterization purpose, a detailed particle optical model of the Muon g-2 Storage Ring [69] has been developed using a computational environment for various advanced concepts of modern scientific computing with specialized application packages in COSY IN-FINITY [53]. The package dedicated to the design and analysis of particle optical systems is employed for the modeling of the storage ring. Differential-algebraic (DA) map methods in COSY INFINITY allow the preparation of transfer maps that describe the solutions of storage ring beam optics ordinary differential equations (ODEs) for arbitrarily complicated fields and to arbitrary order [54]. The manipulation of such transfer maps in COSY IN-FINITY facilitates the characterization of the leading order and nonlinear properties of the storage ring, as well as their action on the dynamics of the injected beam through repetitive tracking. Map methods allow for the incorporation of all measured field effects for these purposes and, in conjunction with COSY INFINITY's parallel computation features, yield fast high-statistics particle tracking in contrast to conventional orbit-integration beam dynamics codes. Symplecticity is enforced in beam tracking with high-order transfer maps in COSY INFINITY to ensure energy conservation and control error propagation [70].

Each of the optical elements that constitute the storage ring is represented by a timedependent transfer map, and their ordered multiplication via map methods result in the assembly of the COSY-based storage ring model. The following elements are the main components of the model (see Fig. 3.1):

1. The electrostatic quadrupole system. The electrostatic fields generated by each of the eight sets of curved electrodes aligned with the design orbit are computed in COSY INFINITY from the field information in the midplane, which was calculated using conformal mapping methods [71]. The geometry of the electrostatic quadrupole system (ESQ) is symmetric with respect to the horizontal midplane, allowing to recreate the 3D electrostatic field immersed in the vertical magnetic field as a Taylor expansion in transversal coordinates [72]. The coefficients of the expansion are automatically computed to satisfy the Laplacian in curvilinear coordinates. The fringe fields and the effective field boundary are modeled based on numerical calculations using

Figure 3.1: Layout of the Muon g-2 storage ring at Fermilab. The four locations of the ESQ are found next to labels "Q1-Q4" (each covering 39° azimuthally) and labels "K1-K3" indicate the place of the injection kicker plates within the ring. "C" labels denote the beam collimators arrangement.

COULOMB [71]. The map representation of the fringe fields is accurately computed with DA methods in COSY INFINITY [72]. The modeling during the scraping and time-dependent stages of the ESQ is handled with transfer maps of the mis-powered ESQ electrodes combined with the maps that describe the main guide fields.

2. Injection kickers. The transversal kicker action on the injected beam is represented via symplectic kicks proportional to the longitudinal lengths and characteristic timedependent strengths of the kickers. Particles within the beam experience the kick individually at the azimuthal center of each kicker station, where the time-of-flight coordinates and turn number establish the degree to which their directions deviate.

3. Magnetic field data. The ppm-level magnetic field inhomogeneities measured by the nuclear magnetic resonance (NMR) probes in the storage ring are fitted with transverse multipole expansion functions to prepare segmented transfer maps of the magnetic field. Magnetic multipole elements encompassing ~ 2 mrad azimuthal sections throughout the ring represented by such maps simulate the azimuthal dependence of the magnetic field. These representations, together with symplectic kicks that recreate the lowest order fits to magnetic field measurements, are superimposed over the uniform portion of the guide fields automatically computed in 3D from the midplane information.

Aperture cuts are applied during repetitive tracking employing special commands of COSY INFINITY's beam physics package, where particles with transverse coordinates beyond the circular apertures of the collimators inserted at specific locations of the storage ring are flagged as lost. High-statistics numerical studies of muon loss rates of the stored muon beam due to betatron resonances are computed with a short turnaround time based on the tools described above. Numerous studies concerning the lowest order and nonlinear dynamics of the muon beam and lattice properties of the storage ring have been performed, such as muon capture efficiency, amplitude-dependent betatron tune shifts, muon beam characterization (spin dynamics, distribution correlations, beam de-coherence, etc.), closed orbit distortions, ring lattice parameterization, and systematic studies and correction calculations of the precession frequency ω_a . The contributions to ω_a where the output of the COSY-based storage ring model played a direct role are presented in Chap. 4. In terms of the Beam Dynamics framework, the main results—and some of them are considered intermediate in view of beam dynamics-driven ω_a and \tilde{B} corrections— of the model are presented in Sec. 3.3 and 3.4 from both the linear and nonlinear front. A nominal characterization (i.e., under nominal operational settings) of the stored muon beam is delineated in Sec. 3.5, whereas the peculiar behavior of the beam during the first official run of the g-2 storage ring (i.e., "Run-1") is described in Sec. 3.6.

3.2 The COSY-based Muon Storage Ring Model

Figure 3.2 illustrates the components, interrelations, and input of the COSY-based Muon Storage Ring Model (or "COSY-based model" for short) as part of the muon g-2 experiment. The main purpose of this model is to express the physics that dictates the dynamics of the muon beam in practical terms, in order to use it for beam characterization (see Sec. 3.3-3.6) and accurate calculations of beam-driven uncertainties (see Chap. 4) in the E989 main measurement. To achieve a trustworthy beam-physics representation of the storage ring, the COSY-based model heavily relies on precise measurements of its guide fields (or data-driven reconstructions of them when not available) and realistic initial beam distributions.

Two initial beam distributions are prepared with different methods. The features of these two inputs are described in Sec. 3.2.5 and 3.6.3.

The physics emerged from the implemented guide fields (see Sec. 3.2.1-3.2.3) is captured as high-order transfer maps. For the preparation of these maps, the beam physics code of COSY INFINITY integrates the ordinary differential equations of motion (ODEs) in particle optical coordinates with an eighth-order Runge-Kutta integrator over a differential algebra (DA) $_{n}D_{v}$, where *n* is the computation order and *v* is the number of phase space coordinates [72]. The result is a transfer map \mathcal{M} used to obtain the z_{f} coordinates of any

Figure 3.2: Flow chart of the COSY-based Muon Storage Ring Model. Experimental measurements constitute the guide fields as defined in the model, whose main output is nonlinear transfer maps for the calculation of optical lattice functions and beam orbital (and spin) symplectic tracking. With special methods explained in this chapter, guide fields are reconstructed and initial beam distributions are recreated for a detailed characterization of the muon beam in the g-2 storage ring. The characterization is further used for quantifications of beam dynamics systematic corrections in the g-2 final measurement.

particle based on its initial conditions:

$$\vec{z}_f = \mathcal{M}(\vec{z}_i). \tag{3.1}$$

Besides performing long-term beam tracking, the resulting maps are further used and manipulated for tracking-independent formulations of the storage ring optical lattice (e.g., beta functions, dispersion functions, and closed orbits, and betatron tunes) as well as amplitudeand momentum-dependent tune shifts (see Sec. 3.3-3.6).

3.2.1 The electrostatic quadrupole system

The electrostatic quadrupole system (ESQ) is a four-fold azimuthally symmetric system (see Fig. 3.1) with four plates centered around the ideal orbit [73] (see Fig. 3.3) meant to supply vertical beam focusing, but at the cost of horizontal defocusing and nonlinear beam dynamics effects due to the specific geometry of the plates. Each ESQ station consists of

Figure 3.3: Photograph of one ESQ station. For vertical confinement of (positive) muons, the top and bottom plates are positively charged whereas the lateral plates are charged with negative voltage. The vertical magnetic field in the storage ring largely contributes to stable motion in the horizontal direction, in spite of the defocusing radial gradient from the ESQ inner and outer plates.

a short and long section separated by 4°, and extended by azimuthal lengths of 13° and 26°, respectively. Together with the vacuum chambers, all the ESQ was adopted from the previous E821 experiment at BNL. The plates are made with aluminum graded such that their low magnetic susceptibility and thicknesses do not interfere either with the overall magnetic field quality nor the calorimeters energy resolution (as decay positrons trajectories often cross the lateral plates). The four-fold symmetry, inherited from E821, was chosen to

accommodate instrumentation in-between the stations and, simultaneously, minimize beam variations (i.e., less than 3%) around the ring.

The ESQ plates play the role of electrodes while being charged by power supplies via high-voltage resistors; the circuitry involved to carry the voltage to the plates is configured to deliver charge to them every 700 μ s in one or two steps. To generate closed orbit distortions (see Sec. 3.3.3) for beam scraping purposes, a specific set of plates (i.e., all bottom plates, inner plates at Q2, and outer plates at Q4) is connected to the 2-step pulsers, which rise initially from 0 to about 6 kV below the nominal High-Voltage (HV) setpoint (see Fig. 3.4). The rising times are such that these mis-powered plates reach a steady HV when the beam

Figure 3.4: Illustration of the HV traces from plates connected to the 1-pulse (red line) and 2-pulse (blue curve) HV supplies. The mis-powered ESQ plates (blue) during the initial $\sim 7 \,\mu s$ after injection shift the beam towards the limiting apertures of the storage volume, in order to scrape the beam in preparation for the data taking period at $t > 30 \,\mu s$.

is injected into the storage ring for about 7 µs, at which point the second pulse takes place to charge them up to the nominal HV value. The transitions from mis-powered to nominal HVs are adiabatic, where the resistors connected to the plates are chosen to yield transition times of $\tau_C = RC \approx 5 \,\mu s$. The total to-ground capacitance of the plates, on the order of $100 - 300 \,\mathrm{pF}$ [74], are not easily malleable since they surge from several properties on the grounding, intervened by HV leads, feed-throughs, plates geometry, etc. Since $\tau_C \gg T_C$ (where $T_C \approx 0.1492 \,\mu s$ is the cyclotron period), beam tracking simulations are reliably performed with one-turn transfer maps prepared per cyclotron period. After commissioning, the typical HV setpoints of the first g-2 runs (HV~ 18 kV) were chosen so that the ESQ can stably run without discharging sparks and, on the other hand, to try to avoid betatron resonances. The resulting focusing/defocusing electric fields reach values on the order of $6 \,\mathrm{kV/cm}$.

Due to the longitudinal curvature and overall geometry of the ESQ electrodes, the generated electric fields exhibit nonlinear features whose effect is perceived more noticeably near the limits of the storage volume, as shown in Fig. 3.5. To reproduce a realistic representa-

Figure 3.5: Radial electric field along the midplane (HV= 18.3 kV). Near the aperture limits at x = 45 mm, nonlinearities from the ESQ electric fields distort the otherwise linear radial field.

tion of the ESQ electric fields, the transverse electrostatic potential is defined as a transverse Taylor expansion in the radial-vertical (or, equivalently, x-y) plane at a longitudinal location

s:

$$V = V(x, y, s) = \sum_{k=0}^{\infty} \sum_{l=0}^{\infty} a_{k,l}(s) \frac{x^k y^l}{k! l!}.$$
(3.2)

By exploiting the horizontal-plane symmetry of the ESQ station's cross section, all the $a_{k,l}(s)$ coefficients are uniquely determined out of the midplane coefficients $a_{k,0}(s)$ as follows [60]:

$$a_{k,l+2} = -a_{k,l}'' - kha_{k-1,l}'' + kh'a_{k-1,l}' - a_{k+2,l} - (3k+1)ha_{k+1,l} - 3kha_{k-1,l+2} - k(3k-1)h^2a_{k,l} - 3k(k-1)h^2a_{k-2,l+2} - k(k-1)^2h^3a_{k-1,l} - k(k-1)(k-2)h^3a_{k-3,l+2},$$
(3.3)

where h is the inverse of the station curvature radius (7.112 m) and $a'_{k,l} = da_{k,l}/ds$. The resulting set of coefficients satisfies Laplace's equation in curvilinear coordinates to ensure a Fully Maxwellian field. The $a_{k,0}$ coefficients at the main ESQ field region are calculated with conformal mapping methods [71] and specified in COSY INFINITY, which computes the fields from a 3D out-of-plane expansion via DA methods [75] for the computation of transfer maps.

Table 3.1 shows the $a_{k,l}$ terms specific to a nominal ESQ station charged at HV= 18.3 kV.

The four-fold symmetric geometry of the plates around the station center favors the presence of the leading quadrupole (k=2), 12 pole (k=6), 20 pole (k=10), and further 4(2i - 1) pole midplane-symmetric (l=0) terms, being the quadrupole term—which largely defines the betatron tunes of the ring—about 3.4% higher than the voltage applied to the plates [76]. Of special interest is the 20 pole, whose larger relative magnitude manifests itself in betatron resonance and tune shifts, as elaborated in the next chapter. Figure 3.6 shows the overall and nonlinear structures of the electrostatic potential from a charged ESQ station implemented in the COSY-based model.

The effective field boundary ($z_{EFB} = 1.2195 \,\mathrm{cm}$) and fringe fields of the ESQ are calculated using COULOMB's [50,71] boundary-element method field solver. Figure 3.7 shows

Table 3.1: $a_{k,0}$ coefficients at the main ESQ field region (see Eq. (3.3)) for HV= 18.3 kV, scaled by $r_0^{k+l}/k!l!$ ($r_0 = 5 \text{ cm}$). Due to the ESQ midplane symmetry, coefficients with odd l values are zero.

the resulting fringe field falloff, which is implemented in the COSY-model ESQ transfer maps via an Enge-function:

$$F(z) = \frac{1}{1 + \exp\left(a_1 + a_2 \cdot (z/D) + \ldots + a_6 \cdot (z/D)^5\right)},$$
(3.4)

where D is the full aperture of the ESQ (D = 10 cm) and the Enge coefficients are

$$a_1 = 0.14389529, \quad a_2 = 6.85939851, \quad a_3 = -1.87096936,$$

 $a_4 = 0.80158053, \quad a_5 = -0.40704326, \quad a_6 = 0.06588881.$ (3.5)

With the fringe fields falloff, the leading electric multipole coefficient strengths are scaled accordingly and the longitudinal dependencies are captured recursively in COSY INFINITY for the ESQ modeling. The effective field boundary for this specific case elongates the field extension of each station, reducing radial tunes by $\sim 0.07\%$ and increasing the vertical ones

Figure 3.6: Main electrostatic potential [kV] from an ESQ station on the left side, overlaid with electric vector field represented with arrows. On the right, electrostatic potential from higher order terms in the Taylor expansion; the curvature of the plates and the presence of the 20 pole are manifested near the limiting bounds of the storage region.

by $\sim 0.05\%$ with respect to a hard-edge case.

Two of the 32 HV resistors connected to the ESQ plates were damaged during the first data-taking run ("Run-1") of the muon g-2 experiment. Consequently, the resulting electric fields exhibited special behaviors that affected the transverse stability of the stored beam, as described in Sec. 3.6.

For the transfer maps preparation in the COSY-based model, the ODEs subject to the ESQ electric fields described above also account for the embedding magnetic field in the storage ring. The implementation and features of the magnetic fields in the COSY-based model are described next.

3.2.2 Magnetic field data

The subtle imperfections of the magnetic field within the storage region of the ring drive closed orbit distortions and betatron resonances at specific high-voltage settings of the ESQ.

Figure 3.7: Longitudinal fringe field at an ESQ station edge. The effective field boundary extends the occupancy of the electric fields in the hard-edge view by $\sim 0.436\%$.

In our model, such inhomogeneities are included based on fits of nuclear magnetic resonance (NMR) trolley run measurements from the g-2 Field Team. The azimuth-independent fits provide the extraction of 2D magnetic normal and skew multipole coefficients (up to the decapole term) by attributing the scalar measurements to the predominant vertical magnetic field.

By considering Laplace's equation in cylindrical coordinates and omitting azimuthal z variations of the magnetic potential V,

$$\nabla V(r,\theta,z) = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial V}{\partial r}\right) + \frac{1}{r}\frac{\partial}{\partial \theta}\left(\frac{1}{r}\frac{\partial V}{\partial \theta}\right) = 0, \qquad (3.6)$$

the vertical magnetic field is expressed as a summation of magnetic multipole coefficients:

$$B_y(r,\theta) = v_0 + \sum_{n=1}^{\infty} \left(\frac{r}{r_0}\right)^n \left[v_n \cos n\theta + w_n \sin n\theta\right].$$
(3.7)

In Eqs. (3.6) and (3.7), $r = \sqrt{x^2 + y^2}$ is the transverse distance from the design orbit and

 r_0 is the reference radius of the multipoles. The angle θ is the counterclockwise angle from the x axis such that $\cos \theta = x/r$.

Since the NMR measurements of the scalar magnetic field are insensitive to its direction and, on the other hand, the field is known *a priori* to be dominantly vertical, a sensible approximation of taking B_y as the scalar field itself yields

$$B(r,\theta) \approx B_y(r,\theta) = B_0 \left(b_0 + \sum_{n=1}^{\infty} \left(\frac{r}{r_0} \right)^n \left[b_n \cos(n\theta) + a_n \sin(n\theta) \right] \right).$$
(3.8)

Due to the ppm-level radial and longitudinal components of the magnetic field in the storage ring [40], this approach adds a small error of only ~ 10 ppb to NMR measurements [77]. In the determination of the field, the main errors originate from field transients, temperature fluctuations, motional effects, calibration and positioning uncertainties of the probes that map the field within the storage volume (refer to [39]). However, thanks to the high uniformity of the field to some extent, such errors were small for Run-1, i.e., ~ $\mathcal{O}(100 \text{ ppb})$ relative to the main dipole field and are expected to be reduced for Run-2 and posterior runs.

The relative strengths of the magnetic multiple components implemented in the COSYbased model are shown in Fig. 3.8 and follow the notation in [78]:

$$\Delta B_y + i\Delta B_x = B_0 \sum_n \left(b_n + ia_n\right) (x + iy)^n.$$
(3.9)

In the model, the transfer map of an ESQ station of azimuthal length L with magnetic field inhomogeneities within $(\mathcal{M}_{E,B})$ is prepared as a sequence of adjacent optical elements

Figure 3.8: Magnetic field multipoles from Trolley Run 3956. All the multipole terms are expressed relative to the ideal vertical magnetic field B_0 that sustains magic muons in the ideal orbit. The skew dipole term (also called radial field) was measured with a Hall probe in 2016 [40] and averaged out to recreate the expected effect of the surface correction coils (SCC).

as follows:

$$\mathcal{M}_{E,B}(L) = \left(\mathcal{M}_E(L_i/2) \cdot \mathcal{M}_L(-l) \cdot \mathcal{M}_B(\phi, l) \cdot \mathcal{M}_E(L_i/2) + \mathcal{C}_x(L_i, \phi) + \mathcal{C}_y(L_i, \phi)\right)^n.$$
(3.10)

The map $\mathcal{M}_E(L_i)$ encapsulates the Fully Maxwellian ESQ electric fields (see Sec. 3.2.1) embedded in the ideal vertical magnetic field $B_0 = p_{\mu}/e\rho_0$ where p_0 is the magic momentum, ethe elementary charge, and the design radius is $\rho_0 \approx 7.112$ m. The azimuthal length L_i (typically about 0.1°) is chosen so that the final map length corresponds to L and the azimuthal variation of the magnetic multipoles is captured. By virtue of the thin lens approximation and the significantly small sizes of the magnetic field inhomogeneities relative to the main vertical field— an element $\mathcal{M}_B(\phi, l)$ with a superposition of the azimuthally dependent normal and skew magnetic multipoles at the azimuth ϕ acts on the map to cover the effects of the magnetic field errors; the length l is equal to 1 µm and the multipoles are properly scaled. A multi-Gaussian function is implemented to calculate the magnitudes of the measured magnetic multipoles at any azimuth. A drift element $\mathcal{M}_L(-l)$ of negative length is defined for counteracting the nonzero length of $\mathcal{M}_B(\phi, l)$. The low-order skew and normal magnetic coefficients, a_0 and b_0 , are modeled as symplectic kicks and act on the constant part (written explicitly as \mathcal{C}_x and \mathcal{C}_y in Eq. (3.10)) of the transfer map so that

$$\Delta a = -B_0 b_0 L_i / \chi_m \quad , \quad \Delta b = B_0 a_0 L_i / \chi_m, \tag{3.11}$$

where $\chi_m = B_0 \rho_0$ is the magnetic rigidity. Δa and Δb are the radial and vertical direction offsets in particle optical coordinates. To preserve the Hamiltonian (via phase-space preservation) during beam tracking simulations with this detailed implementation of the subtle magnetic field errors, the symplectic condition is enforced in COSY INFINITY.

3.2.3 Injection kicker magnets

Three kicker stations (see Fig. 3.9) 1.27 m long and about 1/4 of radial betatron wavelength downstream of the inflector exit, where the beam enters the ring, are installed in the storage ring (see Fig. 3.1) for beam injection. The muon beam emerges ~ 77 mm tangentially shifted from the ideal orbit. In order for the injected muons to end up within the ring storage volume, the kicker stations are required to steer them about 10.5 mrad radially outward. To this end, the kicker plates supply an integrated magnetic field of 1.1 kG.m oppositely directed to the vertical field of the storage ring. The kicker stations need to pulse at 100 Hz synchronized to the 120 ns pulse train from the beamlines (see Fig. 2.2), and shut off before

Figure 3.9: Transverse view of a kicker station. The plate geometry is designed to maximize current-to-field conversion in the storage region.

the pulse revolves the 149 ns-long storage ring [79]. In view of these timing specifications, a robust pulser and low-impedance kicker stations are desired to meet the required rise and decay times.

Due to impedance mismatch, the temporal shape of the kicker strengths exhibits a ringing structure as the signal is reflected after the main transient field is induced. Figure 3.10 shows a typical sample during the first run of the muon g-2 experiment [80].

In the COSY-based model, each injected muon is deflected at each longitudinal center of the three kicker stations per turn. The steering is applied as symplectic kicks in both radial and vertical directions:

$$\Delta a(x,y,t) \approx -\frac{e\Delta L}{p_0} B_y^k(x,y,t) \quad , \quad \Delta b(x,y,t) \approx \frac{e\Delta L}{p_0} B_x^k(x,y,t), \tag{3.12}$$

where ΔL is the design kicker length. The transverse structure of the transient field \vec{B}^k is

Figure 3.10: Representative kicker strength pulse during the first run of the muon g-2 experiment, measured with a magnetometer.

based on available *OPERA* simulations of the x-y kickers geometry enclosed by the storage ring vacuum chamber [81]; Fig. 3.11 shows the vector field. The time dependence of \vec{B}^k is captured based on magnetometer measurements of the kicker strength (see Fig. 3.10), scaled according to the specific kicker settings of the g-2 data period being analyzed; typical summed kicker strengths during the first production runs were around 130 kV. Further improvements can be made on the implementation of Eqs. (3.12), namely multiple scaled kicks along each kicker station and the addition of momentum-offset dependence.

For spin tracking, a 3 × 3 rotation matrix $R(\vec{z}_i)$ (due to electric \vec{E}' and magnetic \vec{B}' fields) to act on the initial $\vec{s}_i = (s_x, s_y, s_z)$ spin coordinates of muons in optical coordinates $\vec{z}_i = (x_i, a_i, y_i, b_i, l_i, \delta)$ (see Sec. 3.3 for a definition of the coordinates) is obtained from the

Figure 3.11: Cross section of the magnetic field implemented in the COSY-based model for tracking. The field is stronger near the plate edges and uniform around the center, to deflect muons radially outward.

T-BMT equation [47]

$$\vec{\omega}_S' = -\frac{e}{m} \left\{ \left(\frac{1}{\gamma} + a_\mu \right) \vec{B}' - a_\mu \frac{\gamma}{1+\gamma} \left(\vec{\beta} \cdot \vec{B}' \right) \vec{\beta} - \left(a_\mu + \frac{1}{1+\gamma} \right) \frac{1}{c} \vec{\beta} \times \vec{E}' \right\}$$
(3.13)

where $\vec{\omega}'_S$ is the spin precession frequency in the laboratory frame. The \vec{z} variable δ is the particle momentum offset relative to p_0 and l is proportional to the time of flight relative to the maximum peak of the beam's time profile, which coincides in turn with the maximum kicker strength at station K2 in COSY-based tracking injection studies. The timing between these two profiles is not easily determined, although no offset between them is a good proxy for storage fraction optimization.

In the Frenet-Serret frame relative to the reference particle, the axis of rotation vector \vec{u} of the spin-rotation matrix is defined from Eq. (3.13). Further expressing the instantaneous

precession angle θ' in terms of a differential arc-length advance, the matrix is defined as

$$R(x, a, y, b, \delta) = \begin{pmatrix} \cos\theta' + u_x^2 \left(1 - \cos\theta'\right) & u_x u_y \left(1 - \cos\theta'\right) - u_z \sin\theta' & u_x u_z \left(1 - \cos\theta'\right) + u_y \sin\theta' \\ u_y u_x \left(1 - \cos\theta'\right) + u_z \sin\theta' & \cos\theta' + u_y^2 \left(1 - \cos\theta'\right) & u_y u_z \left(1 - \cos\theta'\right) - u_x \sin\theta' \\ u_z u_x \left(1 - \cos\theta'\right) - u_y \sin\theta' & u_z u_y \left(1 - \cos\theta'\right) + u_x \sin\theta' & \cos\theta' + u_z^2 \left(1 - \cos\theta'\right) \end{pmatrix}$$
(3.14)

where

$$u_x = \frac{\omega'_{Sx}}{\omega'_S} \quad , \quad u_y = \frac{\omega'_{Sy}}{\omega'_S} \quad , \quad u_z = \frac{\omega'_{Sz}}{\omega'_S} \tag{3.15}$$

and

$$dt = \frac{dL}{v} = \left(1 + \frac{x}{\rho_0}\right) \frac{ds_0}{v} \quad \Rightarrow \quad \theta' = \omega'_S dt = \omega'_S \left(1 + \frac{x}{\rho_0}\right) \frac{ds_0}{v}.$$
 (3.16)

The notation ds_0 refers to the nominal arc-length advance in a time interval dt; ρ_0 is the deflection radius, v the particle speed, and x the radial offset relative to the design orbit. In terms of optical particle coordinates, momenta p_i and $\beta_i = v_i/c$ can be defined in terms of \vec{z}_i coordinates:

$$p_x = \gamma m c \beta_x = p_0 a \implies \beta_x = \frac{p_0}{\gamma m c} a = \frac{\gamma_0 \beta_0}{\gamma} a$$

$$p_y = \gamma m c \beta_y = p_0 b \implies \beta_y = \frac{p_0}{\gamma m c} b = \frac{\gamma_0 \beta_0}{\gamma} b \qquad (3.17)$$

$$p_z = \gamma m c \beta_z = p_0 \sqrt{(1+\delta)^2 - a^2 - b^2} \implies \beta_z = \frac{\gamma_0 \beta_0}{\gamma} \sqrt{(1+\delta)^2 - a^2 - b^2},$$

which yield

$$\begin{aligned} \omega_{Sx}' &= -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ \left(\frac{1}{\gamma} + a_\mu\right) B_x' - a_\mu \frac{\gamma}{1+\gamma} \left(\vec{\beta} \cdot \vec{B}'\right) \beta_x - \left(a_\mu + \frac{1}{1+\gamma}\right) \frac{1}{c} \left[\vec{\beta} \times \vec{E}'\right]_x \right\} \\ &= -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ \left(\frac{1}{\gamma} + a_\mu\right) B_x' - a_\mu \frac{(\gamma_0 \beta_0)^2}{\gamma(1+\gamma)} \left(aB_x' + bB_y'\right) a \right. \\ &+ \frac{E_y'}{c} \frac{\gamma_0 \beta_0}{\gamma} \left(a_\mu + \frac{1}{1+\gamma}\right) \sqrt{(1+\delta)^2 - a^2 - b^2} \right\}, \end{aligned}$$

$$(3.18)$$

$$\begin{aligned} \omega_{Sy}' &= -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ \left(\frac{1}{\gamma} + a_\mu\right) B_y' - a_\mu \frac{\gamma}{1+\gamma} \left(\vec{\beta} \cdot \vec{B}'\right) \beta_y - \left(a_\mu + \frac{1}{1+\gamma}\right) \frac{1}{c} \left[\vec{\beta} \times \vec{E}'\right]_y \right\} \\ &= -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ \left(\frac{1}{\gamma} + a_\mu\right) B_y' - a_\mu \frac{(\gamma_0 \beta_0)^2}{\gamma(1+\gamma)} \left(aB_x' + bB_y'\right) b \right\} \\ &- \frac{E_x'}{c} \frac{\gamma_0 \beta_0}{\gamma} \left(a_\mu + \frac{1}{1+\gamma}\right) \sqrt{(1+\delta)^2 - a^2 - b^2} \right\}, \end{aligned}$$

$$(3.19)$$

and

$$\omega_{Sz}' = -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ -a_\mu \frac{\gamma}{1+\gamma} \left(\vec{\beta} \cdot \vec{B}' \right) \beta_z - \left(a_\mu + \frac{1}{1+\gamma} \right) \frac{1}{c} \left[\vec{\beta} \times \vec{E}' \right]_z \right\}$$
$$= -\frac{\gamma_0 v_0}{B_0 \rho_0} \left\{ -a_\mu \frac{(\gamma_0 \beta_0)^2}{\gamma(1+\gamma)} \left(aB'_x + bB'_y \right) \sqrt{(1+\delta)^2 - a^2 - b^2} \right.$$
$$\left. -\frac{\gamma_0 \beta_0}{\gamma} \left(a_\mu + \frac{1}{1+\gamma} \right) \left(a\frac{E'_y}{c} - b\frac{E'_x}{c} \right) \right\},$$
(3.20)

where $\vec{E}' = E'_x \hat{x} + E'_y \hat{y}$ and $\vec{B}' = B'_x \hat{x} + B'_y \hat{y}$. For the injection kickers case, $\vec{B}' = \vec{B}^k$ and $\vec{E}' = 0$.

3.2.4 Beam collimation

The components that define the bounds of the storage volume in the ring are the so-called collimators; see Fig. 3.12. These rings are made of copper, with inner and outer radii of 45 mm and 50 mm respectively. Due to their low magnetic susceptibility of -9.63×10^{-6} , the effect on the surrounding magnetic field when they are inserted or retracted is equally negligible [82].

During the first ~ 50 turns after beam injection, the main purpose of the collimators is to scrape the muons with the largest transverse excursions while the application of asymmetric voltages along the ESQ stations distorts the closed orbits. Furthermore, the circular geometry of the collimators contributes to minimizing muon losses while data is taken by

Figure 3.12: Picture of a collimator inserted around the design orbit.

significantly excluding the nonlinear electric fields from the ESQ beyond the collimator apertures. For the former intent, muons hitting collimators lose rigidity by transferring energy to the collimators, made of copper. Moreover, once these muons start diverging from the storage volume towards the inner side of the ring, they do so quickly enough so that their corresponding emitted positrons do not enter into the signal from which ω_a is extracted.

There are five collimator stations along the storage ring, as shown in Fig. 3.1. During the first run of Fermilab's muon g-2 experiment, only two collimators were inserted around the ideal orbit to compensate for the initially lower-than-nominal kickers injection scheme. Afterward, all the 5 collimators were inserted.

Using tools in COSY INFINITY, the muon beam is treated as an array of vectors which permits to efficiently collimate muons beyond well-defined apertures during tracking.

3.2.5 Initial beam distribution

As explained in Chap. 2, the accelerator complex at Fermilab delivers highly polarized muon bunches to the g-2 storage ring at 100 Hz. A handful of numerical studies with different programs recreated the beam transported along the Muon Campus during the commissioning of the muon g-2 experiment [52, 56, 83], whose coordinated effort allowed to benchmark each package. For betatron resonance scans and momentum-time correlation studies, an external distribution [84] was taken for subsequent beam analysis with the COSY-based storage ring model. This distribution results from transferring G4BEAMLINE numerical simulations [56] at the end of the M5 line through fringe fields to the entrance of the ring backleg iron [85]. The maps of these fields are superimposed with the field through the material-free yoke volume where a superconducting inflector is placed to cancel out the field, accounting for the parameters (e.g., inflector angle and field) that maximize the stored fraction. At this point, the mismatched beam is centered ~ 77 mm radially outward from the ideal orbit. Figure 3.13 illustrates the beam distributions in phase space and momentum-time spread. The initial

Figure 3.13: Simulated beam distribution at the exit of the inflector, after the final focus to pass the beam through the hole in the backleg iron. The beam is mostly tangential to the design orbit and about 77 mm radially outward at injection.

time profile of the beam is set based on measurements from scintillating detectors [35]. Two photomultiplier tubes (PMTs) on the vertical sides of a scintillator read out the resulting light, which is adjusted with density filters to ensure an operational range. Prior to entering the storage ring, the incoming beam crosses the "T0" detector, which measures its intensity and longitudinal profile. For beam tracking simulations, an interpolation to T0 data—from the average of a representative train of eight pulses during the first runs of the experiment replaced the original time profile from the G4BEAMLINE distribution transferred through the inflector (see Fig. 3.14). The maximum peak of the T0 signal is aligned with the rays

Figure 3.14: Representative longitudinal profile of the muon beam as measured by the T0 detector. Its length is desired to be contained within the main peak of the kicker pulse to maximize beam storage. The solid line shows the type of multi-Gaussian interpolation used in the model to recreate the longitudinal profile of the simulated muon beam.

originally with no time-of-flight, and its relative timing with the central kicker maximum strength is set to zero; this proxy relation agrees with the experimental tuning to maximize muon storage via this parameter. The time profile coupled with the injection kicker ringing signals determines the correlation between time-of-flight and momentum of the stored muon beam.

3.3 Linear Beam Dynamics

By treating the g-2 storage ring as an optical system, the beam dynamics framework lays out practical conceptual tools for a thorough characterization of the stored beam. To achieve a full extent of such characterization for further a_{μ} systematic error analysis to the ppb level, the action of nonlinear guide fields on the muon beam needs to be accounted for (see Sec. 3.4). Nevertheless, the consideration of electric and magnetic fields in the storage ring up to first order (i.e., dipole and quadrupole components in a Taylor expansion description of the fields, in terms of the optical particle coordinates) encompasses most of the effects that define the beam orbital motion along the ring. Even though the difficult injection process for the muons to get into the storage ring yields the storage volume (i.e., a mostly circular toroid with sectional radius $r_0 \approx 45$ mm and overall radius $\rho_0 \approx 7.112$ mm) almost full of muons, the small admittance limited by the inserted collimators and a rather weak focusing allows to satisfy the paraxial approximation and, this way, the following linear matrix formalism.

In this regime, the equations of motion are linearized so that the optical coordinates of an individual muon $\vec{z}(\theta_2) = \{x_2, a_2, y_2, b_2, l_2, \delta\}$ are defined by its initial state $\vec{z}(\theta_1) = \{x_1, a_1, y_1, b_1, l_1, \delta\}$, where θ_1 and θ_2 are two azimuthal locations in the ring:

$$z_i(\theta_2) = \sum_{j=1}^{6} (z_i | z_j) \, z_j(\theta_1) + C_i.$$
(3.21)

In Eq. (3.21), z_i is the *i*th coordinate of the vector \vec{z} where x and y are the horizontal and vertical spatial deviations from the reference orbit¹; $a = p_x/p_0$ and $b = p_y/p_0$ are the momentum deviations in x and y relative to the reference momentum p_0 (in this case

¹Reference orbit (also known as ideal orbit) refers to the circular trajectory with radius ρ_0 , fully horizontal, aligned with the storage ring center, and in the vertical center of the ESQ stations.

the magic momentum $m_{\mu}c/\sqrt{a_{\mu}} \approx 3.094 \,\text{GeV/c}$; $l = -(t - t_0)v_0\gamma_0/(1 + \gamma_0)$ a parameter proportional to the time-of-flight $t - t_0$ relative to a reference particle with $t = t_0$, speed v_0 and Lorentz factor γ_0 ; and $\delta = (p - p_0)/p_0$ the momentum deviation. The $(z_i|z_j)$ and C_i terms are coefficients derived from the equations of motion and it is customary to arrange them algebraically in a linear matrix $M(1 \rightarrow 2)$ such that

$$\vec{z}(\theta_2) = M(1 \to 2)\vec{z}(\theta_1), \tag{3.22}$$

or in extended form:

$$\begin{pmatrix} x \\ a \\ y \\ b \\ l \\ \delta \end{pmatrix}_{2} = \begin{pmatrix} (x|x) & (x|a) & (x|y) & (x|b) & (x|l) & (x|\delta) \\ (a|x) & (a|a) & (a|y) & (a|b) & (a|l) & (a|\delta) \\ (y|x) & (y|a) & (y|y) & (y|b) & (y|l) & (y|\delta) \\ (b|x) & (b|a) & (b|y) & (b|b) & (b|l) & (b|\delta) \\ (l|x) & (l|a) & (l|y) & (l|b) & (l|l) & (l|\delta) \\ (\delta|x) & (\delta|a) & (\delta|y) & (\delta|b) & (\delta|l) & (\delta|\delta) \end{pmatrix} \begin{pmatrix} x \\ a \\ a \\ y \\ b \\ b \\ l \\ \delta \\ 1 \end{pmatrix}_{1} + \begin{pmatrix} C_{x} \\ C_{a} \\ C_{y} \\ C_{b} \\ C_{l} \\ C_{\delta} \end{pmatrix}.$$
(3.23)

This formalism permits to treat the g-2 storage ring as an optical lattice made of a sequence of optical elements, where each of these elements is represented with a corresponding matrix defined by the guide fields along its azimuthal span. In the storage ring, there are four types of optical elements in the absence of magnetic field errors or ESQ plate misalignments (see Fig. 3.1 for visualization):

- "DIEQS": Short ESQ station ($\theta_{DIEQS} = 13^{\circ} + 2\theta_{EFB}$ long).
- "DIS": Short magnetic section between a short ESQ station (upstream) and a long ESQ station (downstream) ($\theta_{DIS} = 4^{\circ} 2\theta_{EFB}$ long).

- "DIEQL": Long ESQ station ($\theta_{DIEQL} = 26^{\circ} + 2\theta_{EFB}$ long).
- "DIL": Long magnetic section between a long ESQ station (upstream) and a short ESQ station (downstream) ($\theta_{DIL} = 47^{\circ} 2\theta_{EFB}$ long).

As explained in Sec. 3.2.1, the angle $\theta_{EFB} = z_{EFB}/\rho_0$ accounts for the effective field boundary at the edges of ESQ stations. In this simplified but representative approach, *DIL* and *DIS* are homogeneous sector magnets described [60] by

$$M_{DI}(\theta) = \begin{pmatrix} \cos\theta & \rho_0 \sin\theta & 0 & 0 & 0 & \rho_0(1 - \cos\theta) \\ -\sin\theta/\rho_0 & \cos\theta & 0 & 0 & 0 & \sin\theta \\ 0 & 0 & 1 & \rho_0\theta & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ -\frac{\gamma_0}{\gamma_0 + 1}\sin\theta & -\frac{\gamma_0}{\gamma_0 + 1}\rho_0(1 - \cos\theta) & 0 & 0 & 1 & -\rho_0\left[\frac{\gamma_0 - 1}{\gamma_0}\theta - \left(\frac{\gamma_0}{\gamma_0 + 1}\right)\sin\theta\right] \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix},$$
(3.24)

where θ is the azimuthal length of the sector and $\rho_0 = 7.112$ m the nominal bending radius. In a similar manner, the *DIEQ* elements correspond to inhomogeneous sector magnets [50] where the inhomogeneity index n_e —which introduces a linear dependence to the effective bending field $B_y(x)$ —emerges from the ESQ electric quadrupole gradient:

$$B_y(x) = B_0 \left(1 - n_e \frac{x}{\rho_0} \right) \tag{3.25}$$

$$= B_0 \left(1 - \left[\frac{\rho_0}{v_0 B_0} \frac{\partial E_x}{\partial x} \right] \frac{x}{\rho_0} \right).$$
(3.26)

 $B_0 = p_0/e\rho_0 \approx 1.4513\,\mathrm{T}$ is the vertical nominal field and the radial electric field gradient

 $\partial E_x/\partial x$ horizontally defocuses the positively charged muon beam. The solution of the linearized equations of motion for such optical element produce the following result:

$$M_{DIEQ}(\theta) = \begin{pmatrix} \cos(\sqrt{1-n_e}\theta) & \frac{\rho_0}{\sqrt{1-n_e}}\sin(\sqrt{1-n_e}\theta) & 0 & 0 & 0 & (x|\delta) \\ -\frac{\sqrt{1-n_e}}{\rho_0}\sin(\sqrt{1-n_e}\theta) & \cos(\sqrt{1-n_e}\theta) & 0 & 0 & 0 & (a|\delta) \\ 0 & 0 & \cos(\sqrt{n_e}\theta) & \frac{\rho_0}{\sqrt{n_e}}\sin(\sqrt{n_e}\theta) & 0 & 0 \\ 0 & 0 & -\frac{\sqrt{n_e}}{\rho_0}\sin(\sqrt{n_e}\theta) & \cos(\sqrt{n_e}\theta) & 0 & 0 \\ (l|x) & (l|a) & 0 & 0 & 1 & (l|\delta) \\ 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix},$$
(3.27)

where

$$(x|\delta) = \frac{\rho_0}{1 - n_e} [1 - \cos(\sqrt{1 - n_e}\theta)], \qquad (3.28)$$

$$(a|\delta) = \frac{1}{\sqrt{1-n_e}}\sin(\sqrt{1-n_e}\theta), \qquad (3.29)$$

$$(l|x) = -\frac{\gamma_0}{\gamma_0 + 1} \frac{1}{\sqrt{1 - n_e}} \sin(\sqrt{1 - n_e}\theta), \qquad (3.30)$$

$$(l|a) = -\frac{\gamma_0}{\gamma_0 + 1} \frac{\rho_0}{1 - n_e} [1 - \cos(\sqrt{1 - n_e}\theta)], \text{ and}$$
(3.31)

$$(l|\delta) = -\rho_0 \frac{\gamma_0}{\gamma_0 + 1} \left\{ \left[\frac{1}{1 - n_e} - \frac{1}{(1 + \eta_0)^2} \right] \theta - \frac{1}{(1 - n_e)^{3/2}} \sin(\sqrt{1 - n_e}\theta) \right\}.$$
 (3.32)

With these transfer matrices, the coordinates vector \vec{z} of a muon can be transferred through the ring. For instance, the coordinates $\vec{z_i}$ of a muon upstream of a short ESQ station after n full revolutions evolve according to the repeated action of each ring element as follows:

$$\vec{z}_n = M_n^0 \vec{z}_i = \left(M_{DI}(\theta_{DIL}) \cdot M_{DIEQ}(\theta_{DIEQL}) \cdot M_{DI}(\theta_{DIS}) \cdot M_{DIEQ}(\theta_{DIEQS}) \right)^{4n} \vec{z}_i$$
(3.33)

At HV= $18.3 \,\text{kV}$ (a typical ESQ high voltage during Run-1 of the muon g-2 experiment),

the one-turn matrix M_1^0 is²

$$M_{1}^{0} = \begin{pmatrix} 0.92045E + 00 & -0.25743E + 01 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.48687E + 00 \\ 0.45556E - 01 & 0.95902E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & -0.35324E + 00 \\ 0.00000E + 00 & 0.00000E + 00 & -0.60304E + 00 & 0.18795E + 02 & 0.00000E + 00 & 0.00000E + 00 \\ 0.00000E + 00 & 0.00000E + 00 & -0.41356E - 01 & -0.36936E + 00 & 0.00000E + 00 & 0.00000E + 00 \\ 0.34732E + 00 & -0.44242E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 & -0.49502E + 02 \\ 0.00000E + 00 & 0.10000E + 01 \\ \end{pmatrix}$$

As shown in M_1^0 , the radial and vertical motion in the ring is linearly decoupled (e.g., (x|y) = (x|b) = (y|x) = (y|a) = 0 and any other map components that relate radial and vertical coordinates). Expectedly, the momentum deviation δ is not influenced by the other orbital coordinates (and $C_{\delta} = 0$) being the storage ring a time-independent Hamiltonian system. Furthermore, one can demonstrate that the transverse coordinates x and y do not diverge since

$$|(x|x) + (a|a)| < 2 \quad , \quad |(y|y) + (b|b)| < 2.$$
(3.35)

The map M_1^0 does not account for the ppm-level magnetic field inhomogeneities. When these are introduced in the calculation of the map as explained in Sec. 3.2.2 based on NMRprobe measurements, constant terms (i.e., C_i terms in Eq. (3.23)) emerge. The nonzero terms in M_1^0 slightly change by less than 0.1% as a consequence of the normal quadrupole terms from magnetic field imperfections. And moreover, magnetic skew quadrupole terms add weak coupling between the radial and vertical motion via nonzero (x|y), (x|b), (a|y), (a|b), etc. terms. Such new map M_1' relative to the ideal orbit in the storage ring can be re-expanded around the closed orbit originated by the magnetic field imperfections. Each of

²In the following discussion, δ -related components are sometimes expressed in terms of $\delta_k = (K - K_0)/K_0$ instead, where K is the kinetic energy for compatibility with COSY INFINITY's set of particle coordinates. For the momentum acceptance and reference value in the g-2 storage ring, δ and δ_k do not differ by more than $(\gamma_0 + 1)/\gamma_0 - 1 \approx 3.41\%$.

the $\vec{z}_0(\theta; \delta) = \{x_0(\delta), a_0(\delta), y_0(\delta), b_0(\delta), 0, \delta\}(\theta)$ momentum-dependent fixed points at any azimuth θ that compose this new closed orbit can be found with the following operation:

$$\vec{z}_0(\theta; \delta) = (M'(\theta) - I)^{-1} \vec{0},$$
(3.36)

where I is the identity map, M' is the original map around the reference orbit at θ , and $\vec{0}$ contains the \vec{z} coordinates of the reference orbit $\vec{0} = \{0, 0, 0, 0, 0, 0, \delta\}$.

In order to extract the field index, Twiss parameters, and dispersion functions (See Sec. 3.3.2), as well as to perform symplectic beam tracking and nonlinear calculations, maps such as M'_1 are re-expanded around their corresponding fixed points. This way, the resulting map is origin-preserving (i.e., the vector $\vec{0}$ is unchanged under the action of M). For this purpose, and taking M'_1 as an example, the map around the fixed point M_1 is found as follows:

$$M_1(\theta) = M_1'(\theta) \left(\vec{z}_0(\theta; \delta) + I \right) - \vec{z}_0(\theta; \delta).$$
(3.37)

In the linear regime, $M_1 = M'_1$. However, under the presence of nonlinear terms, that is not the case; nonlinear terms leak inside the linear terms of M_1 when $\vec{z_0}$ is nonzero (refer to Sec. 3.4 for the discussion of nonlinear beam dynamics in the muon g-2 experiment). The resulting one-turn map M_1 for NMR-probe data during the last Run-1 dataset is

$$M_{1} = \begin{pmatrix} 0.92089E + 00 & -0.25742E + 01 & -0.43513E - 03 & -0.23697E - 03 & 0.00000E + 00 & 0.48210E + 00 \\ 0.45431E - 01 & 0.95891E + 00 & 0.26600E - 04 & 0.73226E - 04 & 0.00000E + 00 & -0.35194E + 00 \\ 0.88037E - 03 & 0.65890E - 02 & -0.60221E + 00 & 0.18825E + 02 & 0.00000E + 00 & 0.90815E - 02 \\ -0.13050E - 04 & -0.12671E - 03 & -0.41352E - 01 & -0.36789E + 00 & 0.00000E + 00 & 0.26431E - 03 \\ 0.34600E + 00 & -0.44366E + 00 & -0.35668E - 03 & -0.83647E - 02 & 0.10000E + 01 & -0.49482E + 02 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 \end{pmatrix}.$$
 (3.38)

With these linear maps, beam tracking simulations are plausible with the limitation of overlooking nonlinear effects such as betatron oscillations de-coherence (i.e., nonlinear amplitude- and momentum-dependent tune shifts) and betatron resonance effects (presented in the subsections below). Moreover, the information contained in the $(z_i|z_j)$ terms allows for the characterization of several beam parameters, as shown next.

3.3.1 Betatron tunes

It is customary in the muon g-2 collaboration to parametrize some dynamical properties of the beam by visualizing the storage ring as a single inhomogeneous sector magnet $M_{DIEQ}(360^{\circ})$ (refer to Eq. (3.27)). In this perspective, which is possible thanks to the rather weak focusing in the ring, the field index n_e is scaled by the ESQ stations occupancy in the ring's azimuth to obtain:

$$n = \frac{4(\theta_{DIEQS} + \theta_{DIEQL})}{4(\theta_{DIEQS} + \theta_{DIS} + \theta_{DIEQL} + \theta_{DIL})} n_e = 0.4376998 n_e.$$
(3.39)

During the four Run-1 datasets, the two nominal ESQ voltages were HV = 18.3 kV and HV = 20.4 kV which correspond to the following g-2 field indices:

$$n = 0.108790931$$
 and $0.121275137.$ (3.40)

For comparison purposes with M_1^0 (Eq. (3.34)), at HV = 18.3 kV the representative linear map is

$$M_{DIEQ}(360^{\circ}) = \begin{pmatrix} 0.93882E + 00 & -0.45717E - 01 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.47213E + 00 \\ 0.45717E - 01 & 0.93882E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & -0.35279E + 00 \\ 0.00000E + 00 & 0.00000E + 00 & -0.48084E + 00 & 0.18906E + 02 & 0.00000E + 00 & 0.00000E + 00 \\ 0.00000E + 00 & 0.00000E + 00 & -0.40664E - 01 & -0.48084E + 00 & 0.00000E + 00 & 0.00000E + 00 \\ 0.35279E + 00 & -0.47213E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 \\ 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.00000E + 00 & 0.10000E + 01 \\ \end{pmatrix}.$$

A set of betatron tunes (ν_x, ν_y) —defined as the average number of transverse oscillations per turn—can be calculated from the traces of $M_{DIEQ}(360^\circ)$:

$$\nu_x = \frac{1}{2\pi} \cos^{-1} \left(\frac{(x|x) + (a|a)}{2} \right) = \sqrt{1 - n}$$
(3.42)

$$\nu_y = \frac{1}{2\pi} \cos^{-1} \left(\frac{(y|y) + (b|b)}{2} \right) = \sqrt{n}, \tag{3.43}$$

where for $HV = 18.3 \,kV$:

$$\nu_x = 0.944038701$$
 and $\nu_y = 0.329834703.$ (3.44)

In Table 3.2, relative comparisons with measurements [86] are shown (i.e., $(\nu_x - \nu_x^{data})/\nu_x^{data}$).

Table 3.2: Relative comparisons of computed horizontal tunes with measurements.

HV [kV]	M_{DIEQ}	M_1^0	M_1
18.3	-0.0557%	-0.0108%	-0.0053%
20.4	-0.0701%	-0.0137%	-0.0034%

Radial tunes obtained from the approximated model $M_{DIEQ}(360^{\circ})$, from the ideal ring model (M_1^0) and from a ring with magnetic field inhomogeneities (M_1) differ by less than 0.08% relative to tunes extracted from tracker data during Run-1, being M_1 the most accurate case; accounting for the ±30 ppm background of the normal magnetic quadrupole component yields the superior description of the tunes. As explained in Sec. 3.6, failures in the instrumentation of the ESQ led to time-dependent tunes which evolved by about 0.5% during the measurement period. Thus, for the relative differences in Table 3.2 the stable tunes were extracted from the observed frequencies f_{CBO} of the beam radial betatron oscillation at late times of the fills, where

$$f_{CBO} = f_c(1 - \nu_x) \tag{3.45}$$

and the cyclotron frequency f_c is taken as

$$f_c = \frac{p_0}{2\pi m_\mu \gamma_0 \rho_0} = 6.704958 \,\mathrm{MHz.} \tag{3.46}$$

As explained in [50], fringe fields at the ESQ edges distort the tunes by less than 0.0008%. Other effects such as ESQ plate misalignments which are not considered in the presented models could be the reason for the small deviation from experimental data. By varying the voltage on the ESQ stations, the setpoint to control the set of betatron tunes is adjusted. Figure 3.15 shows several computations of the tunes for several ESQ voltages. It is desired to avoid ESQ voltages that satisfy resonant conditions (see Eq. (3.66)), which under the presence of the high-order components of the ring's main magnetic field and ESQ electric fields could induce unstable transverse motion as explained in Sec. 3.4.

Of particular interest for beam de-coherence and betatron resonance analyses are the

Figure 3.15: Radial (black) and vertical (blue) betatron tunes as a function of ESQ voltage. linear chromaticities $\xi_{x,y}$, defined as

$$\xi_{x,y} \equiv \frac{\Delta\nu_{x,y}}{\delta} \tag{3.47}$$

where $\Delta \nu_{x,y}$ are tune shifts due to a momentum offset δ . To find them, momentumdependent fixed points $\vec{z}_0(\theta; \delta)$ are computed and the diagonal terms of the map relative to the fixed points are used to calculate the momentum-dependent tunes:

$$\nu_x(\delta) = \frac{1}{2\pi} \cos^{-1}\left(\frac{(x|x)(\delta) + (a|a)(\delta)}{2}\right) = \nu_x^0 + \xi_x \delta + \cdots, \qquad (3.48)$$

$$\nu_y(\delta) = \frac{1}{2\pi} \cos^{-1}\left(\frac{(y|y)(\delta) + (b|b)(\delta)}{2}\right) = \nu_y^0 + \xi_y \delta + \cdots .$$
(3.49)

In this way, linear chromaticities for several ESQ voltages are calculated; see Fig. 3.16 for the results.

Figure 3.16: Radial (black) and vertical (blue) linear chromaticities as a function of ESQ voltage.

3.3.2 Optical lattice functions

With the origin-preserving linear transfer maps in hand, periodic functions that define the beam structure at equilibrium can be defined [58]. This parametrization results from the guide fields in the storage ring, which in more general terms is an optical lattice that acts on the muons treated as rays. There are three of such functions commonly used:

$$\alpha_x(\theta) = \frac{(x|x)(\theta) - (a|a)(\theta)}{2\sin 2\pi\nu_x}, \quad \beta_x(\theta) = \frac{(x|a)(\theta)}{\sin 2\pi\nu_x}, \quad \gamma_x(\theta) = -\frac{(a|x)(\theta)}{\sin 2\pi\nu_x}.$$
 (3.50)

The angle θ indicates the azimuthal location in the ring, and the numerator components on the right-hand side are extracted from one-turn maps at θ . The vertical situation is analogous to the vertical case. With the guide fields implementation, the one-turn maps are prepared along the ring azimuth and then rotated around their fixed points for the extraction of the optical lattice functions. $\alpha(\theta)$, $\beta(\theta)$, and $\gamma(\theta)$ can also be transferred with the originpreserving map components between to azimuths, though the former case was chosen for computational efficiency. Figures 3.17 and 3.18 show these lattice functions along the g-2 storage ring for ring configurations during Run-1.

Due to the momentum spread of the stored muon beam, the dispersion function $D_{x,y}(\theta)$ is also necessary to describe the beam. The following periodic condition is satisfied by the dispersion function:

$$\begin{pmatrix} D \\ D' \\ 1 \end{pmatrix} = \begin{pmatrix} (x|x) & (x|a) & (x|\delta) \\ (a|x) & (a|a) & (a|\delta) \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} D \\ D' \\ 1 \end{pmatrix},$$
(3.51)

which implies

$$D_{x}(\theta) = \frac{(1 - (a|a)(\theta))(x|\delta)(\theta) + (x|a)(\theta)(a|\delta)(\theta)}{2 - (x|x)(\theta) - (a|a)(\theta)}.$$
(3.52)

In Figs. 3.19 and 3.20 dispersion functions for several storage ring settings are presented. The longitudinal derivative of the dispersion function, D', relates to the effect of momentum offsets on a and b, and is not relevant for the characterization intended in this dissertation.

For the beam extrapolation around the ring based on beam diagnosis at two azimuthal locations, the following relations between beam widths (interpreted as RMSs and symbolized with σ) and lattice functions are used:

$$\sigma_x^2(\theta, t) = \varepsilon_x(t)\beta_x(\theta, t) + D_x^2(\theta, t)\sigma_\delta^2, \qquad (3.53)$$

where the time dependence of the width, β and dispersion functions emerge from evolving guide fields, such as Run-1 during production period (see Sec. 3.6). The momentum distribution spread σ_{δ} is obtained from Fast Rotation analysis [87]. From realistic simulations

Figure 3.17: Radial α , β , and γ functions at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plots HV = 18.3 kV, whereas HV = 20.4 kV for plots on the right side. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.

Figure 3.18: Vertical α , β , and γ functions at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plots HV = 18.3 kV, whereas HV = 20.4 kV for plots on the right side. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.

Figure 3.19: Radial dispersion function at 5 μ s (red curves), 20 μ s (green curves), and 1000 μ s (black curves). The ESQ voltage is equal to HV = 18.3 kV on the left-side plot, whereas HV = 20.4 kV for the plot on the right side. Inhomogeneities in the normal quadrupole term of the magnetic field break the four-fold symmetry.

Figure 3.20: Vertical dispersion function at $5 \,\mu s$ (red curves), $20 \,\mu s$ (green curves), and $1000 \,\mu s$ (black curves). On the left-side plot HV = $18.3 \,\text{kV}$, whereas HV = $20.4 \,\text{kV}$ for the plot on the right side. As the magnetic field is mostly oriented vertically, vertical dispersions are negligible.

with the COSY-based model, in worst-case scenarios accounting for muon scraping, σ_{δ} varies by less than 0.8% during the muon fill; the sensitivity level of radial widths to this scale of momentum spread variations is small compared to the overall azimuthal width modulations, i.e., on the order of 0.03 mm. For the analogous vertical case, the dispersion from measured magnetic gradients is negligible (see Fig. 3.20) for the beam characterization. The transverse emittance ε_x is the RMS of the beam distribution in phase space:

$$\varepsilon_x = \sqrt{\langle x^2 \rangle \langle a^2 \rangle - \langle xa \rangle^2}.$$
(3.54)

With the two straw tracking detectors data of the beam transverse coordinates over time together with Eq. (3.53), the emittance is quantified, allowing to project the beam widths in this way. For vertical width projections, tracker data at only one location is sufficient since $D_y \approx 0$.

The main modulations of the lattice functions are produced by the ESQ electric field and the vertical magnetic field. Magnetic field imperfections mostly from the normal quadrupole component contribute to additional modulations in the optical functions, of about 0.5% or less in relation to the case of a perfect magnetic field (see Figs. 3.21 and 3.22). Since the extracted multipole coefficients from trolley data (except dipole terms) changed by less than 100 ppb relative to B_0 , the extra distortions from magnetic field imperfections are not expected to change on a run-by-run basis. On the other hand, ESQ plate misalignments can add gradient errors as well. An external analysis based on alignment survey data [88] have determined them to be similar in size as distortions from magnetic field inhomogeneities are necessary for the beam means and widths calculation around the ring; the effects from ESQ

Figure 3.21: Beta function distortions from magnetic field inhomogeneities at $5 \,\mu s$ (red curves), $20 \,\mu s$ (green curves), and $1000 \,\mu s$ (black curves) for HV = $18.3 \,\mathrm{kV}$.

plate misalignments are treated as errors.

Figure 3.22: Dispersion function distortions from magnetic field inhomogeneities at 5 μ s (red curves), 20 μ s (green curves), and 1000 μ s (black curves) for HV = 18.3 kV. The plot on the right side shows the total distortion in the vertical dispersion function, which is equal to zero in the nominal case, whereas on the left side the relative distortion of the radial dispersion function is displayed.

The framework provided by the β and dispersion functions as used in Eq. (3.53) is well consolidated for beams with elliptical distributions in phase space and matched—i.e., aligned—with the invariant ellipse of the machine (in this case the storage ring) around the fixed point, defined by:

$$\gamma_x(x - D_x\delta)^2 + 2\alpha_x(x - D_x\delta)(a - D'_x\delta) + \beta_x(a - D'_x\delta)^2 = A, \qquad (3.55)$$

where A is a constant. Due to the challenging beam injection, the stored beam is mismatched to the invariant ellipse. As a result, coherent betatron oscillations (which mostly vanish at late times of the measurement-period cycles) produce temporal beating around the lattice functions. In spite of the mismatching, the lattice functions recreate the beam modulations around the ring for ω_a systematic corrections and the muon weighting, as explained in Sec. 3.5. The other ingredients for a full description of the muon beam along the azimuth are closed orbit distortions presented next.

3.3.3 Closed orbits

As defined in this section and within the framework of transfer maps, closed orbits are the set of fixed points $\vec{z}_0(\theta; \delta)$ for $0 \leq \theta < 2\pi$ that remain unchanged after being transferred around one full revolution $(M'(\theta)\vec{z}_0(\theta; \delta) = \vec{z}_0(\theta; \delta))$. These are obtained via $\vec{z}_0(\theta; \delta) = (M'(\theta) - I)^{-1}\vec{0}$ for $(M'(\theta) - I)$ invertible, as in the g-2 ring case. When the muon coordinates coincide with those of a fixed point, it follows the trajectory defined by the closed orbit in the absence of external perturbations. Furthermore, for a stable system (see Eq. (3.35)), muons within the dynamic aperture and apart from the closed orbit oscillate around it by virtue of the guide field restoring forces. In the linear case, the matched muon beam can be

statistically averaged to a centroid $\bar{z}(\theta, \delta)$ and its spatial coordinates will obey

$$\bar{x}(\theta,\delta) = x_0(\theta,\delta),$$

$$\bar{y}(\theta,\delta) = y_0(\theta,\delta).$$
(3.56)

Due to the small momentum acceptance in the g-2 case, an explicit distinction from the momentum-dependent fixed point can be made with sufficient precision, by accounting for the linear momentum dependence of the fixed point:

$$\bar{x}(\theta) = x_0(\theta) + D_x(\theta)\delta,$$

$$\bar{y}(\theta) = y_0(\theta).$$
(3.57)

Similar to the beam widths case, a mismatched beam exhibits transverse oscillations of its centroids around the closed orbit. In this case, the individual betatron (i.e., transverse) amplitudes $A_{x,y}\sqrt{\beta_{x,y}}$ of the stored muons move coherently per turn N:

$$x(\theta, N) = x_0(\theta) + D_x(\theta)\delta + A_x\sqrt{\beta_x(\theta)}\cos(2\pi\nu_x N + \phi_x),$$

$$y(\theta, N) = y_0(\theta) + A_y\sqrt{\beta_y(\theta)}\cos(2\pi\nu_y N + \phi_y).$$
(3.58)

From the harmonic transverse motion in Eq. (3.58), which results from the linear ODEs with the form of Hill's equations³, oscillations of the mismatched beam centroids and widths emerge. As explained in Sec. 3.4, the coherent modulations tend to de-cohere after beam injection where nonlinear amplitude- and momentum-dependent tune shifts play a significant role.

There are two mechanisms that drive closed orbit distortions relative to the ideal orbit,

³ As explained in Sec. 3.4.3, nonlinearities drive betatron amplitude modulations for which cases Eq. (3.58) does not apply.

namely, the asymmetric ESQ voltage application during the first turns after beam injection (see Sec. 3.2.1) for intentional collimation is one of them and the presence of magnetic and electric steering errors.

In the former case, the imbalance between voltages from top/bottom and inner/outer ESQ plates induce an electric skew and normal dipole component, respectively. The effect is implemented as constant symplectic terms that act on the transfer map as (see Eq. (3.21))

$$C_{a,b} = -\frac{\Delta V}{D_e} b_0 \frac{e\Delta l}{p_0 v_0},\tag{3.59}$$

where $\Delta V = V_0 - V'$ is the difference between nominal and mis-powered voltages (e.g., $V_0 = 18.3 \,\mathrm{kV}$ and $V' = 13.3 \,\mathrm{kV}$ for several Run-1 datasets), $D_e = 5 \,\mathrm{cm}$ is the ESQ aperture, and $b_0 = 0.34428$ is the normal dipole term for one top/bottom ESQ plate at 1 V and the others at 0 V [89]. The Δl term is the ESQ segment length over which the additional dipole term is applied (~ 1 cm in the implementation). Once the regular one-turn map is prepared in this manner at several azimuthal locations, their x_0 and y_0 fixed points are calculated with Eq. (3.36) which all together compose the radial and vertical closed orbits. Figures 3.23 and 3.24 displays closed orbits during collimation in red color. The other mechanism through which the ideal orbit is distorted, steering field errors, are driven mostly by the electric and magnetic normal/skew terms (see Sec. 3.2.2). Figure 3.25 shows closed orbit distortions during Run-1, where the magnetic multipole coefficients were taken from four trolley runs at each Run-1 dataset, named (and ordered in chronological order) as 60h(1a), HK (1b), 9d (1c), and EG (1d). The radial closed orbit evolved due to temperatureinduced instabilities in the normal magnetic field, and similarly for the vertical case, whose effect on the overall vertical shift is determined from positrons vertical data as recorded by

Figure 3.23: Radial closed orbits ($\delta = 0$) at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plot HV = 18.3 kV, whereas HV = 20.4 kV for the plot on the right side. The intentional stretching of the orbit during scraping increases the probability of outermost muons to hit a collimator and, in this way, minimize muon loss rates.

Figure 3.24: Vertical closed orbits ($\delta = 0$) at 5 µs (red curves), 20 µs (green curves), and 1000 µs (black curves). On the left-side plot HV = 18.3 kV, whereas HV = 20.4 kV for the plot on the right side. The induced skew dipole ESQ field created from the HV imbalance between the top/bottom plates shifts the vertical closed orbit for beam scraping.

Figure 3.25: Representative closed orbits during the datasets of the first run (Run-1) of the experiment (60h (1a), HK (1b), 9d (1c), and EG (1d)). Fluctuations in temperature affected the dipole terms of the magnetic field, which led to different closed orbits per Run-1 dataset.

calorimeters; the azimuthal average of the implemented skew dipole field $\langle B_0 a_0 \rangle$ is tuned to match these measurements, where a vertical offset of 1 mm corresponds to $\langle a_0 \rangle \approx 19.5$ ppm. It is assumed in these calculations that for the first Run-1 dataset $\langle a_0 \rangle \approx 0$, which recreates the expected case of the surface correction coils (SCC) averaging out the radial field.

3.4 Nonlinear Beam Dynamics

Similar to the linear map components described to this point, nonlinear map terms are also calculated by integration of the ODEs where higher order relations are considered [72]. The nonlinear map \mathcal{M} , computed to order n, transfers the initial particle coordinates $\vec{z}(\theta_1)$ at θ_1 to its final state $\vec{z}(\theta_2)$:

$$\vec{z}(\theta_2) = \mathcal{M}(1 \to 2)\vec{z}(\theta_1). \tag{3.60}$$

In this extended regime, the transfer map $\mathcal{M} = \{\mathcal{M}_x, \mathcal{M}_a, \mathcal{M}_y, \mathcal{M}_b, \dots\}$ is treated as a collection of DA vectors in COSY INFINITY and equivalent to the following Taylor polynomial

expansion:

$$z_{i}(\theta_{2}) = \sum_{j_{1}=0} \cdots \sum_{j_{6}=0} \left(z_{i} \mid x^{j_{1}}a^{j_{2}}y^{j_{3}}b^{j_{4}}l^{j_{5}}\delta^{j_{6}} \right) (x^{j_{1}}a^{j_{2}}y^{j_{3}}b^{j_{4}}l^{j_{5}}\delta^{j_{6}})(\theta_{1}).$$

$$= C_{i} + \sum_{j=1}^{6} \left(z_{i} \mid z_{j} \right) z_{j}(\theta_{1})$$

$$+ \sum_{j_{1}+\dots+j_{6}\geq 2} \left(z_{i} \mid x^{j_{1}}a^{j_{2}}y^{j_{3}}b^{j_{4}}l^{j_{5}}\delta^{j_{6}} \right) (x^{j_{1}}a^{j_{2}}y^{j_{3}}b^{j_{4}}l^{j_{5}}\delta^{j_{6}})(\theta_{1}).$$

$$(3.61)$$

The summations over j_1, j_2, \ldots, j_6 start at zero (constant terms) and go up to the order n = 10 (i.e., terms with $\sum_{i=1}^{6} j_i \leq 10$) in the presented analysis, which is found to be sufficient to capture all the relevant high-order contributions for nonlinear effects, such as the 20 pole from the ESQ electrostatic field.⁴ Nonlinear contributions $\mathcal{O}(2)$ are captured in the terms of the last line of Eq. (3.61); due to their relatively smaller effect on the muons motion when sufficiently away from betatron resonances, they can be treated as aberrations or corrections to the linear system of the g-2 storage ring. Nevertheless, the understanding of experimental observations and the high level of precision demanded for the E989 measurement requires the characterization of the nonlinear motion. In particular, nonlinear detuning, betatron resonances, and nonlinear-driven muon losses are elaborated next.

3.4.1 Momentum- and amplitude-dependent tune shifts

From design, the further muons move away from the closed orbit, and the more they deviate from the nominal momentum, the stronger the influence of guide field nonlinear components on their dynamics becomes. This can be seen in Eq. (3.61); as $z_i \to \infty$, the nonlinear poly-

 $^{^{4}}$ Nonlinear terms are also included in Eq. (3.37) and in any re-expansion of maps around fixed points.

nomial coefficients gain an increasing weight in the transformation of $\vec{z}(\theta_1)$. Thus, betatron tunes are no longer subject to only the usual effects from linear forces. The COSY-based environment, COSY INFINITY, allows to capture the effects of nonlinearities on betatron tunes via its differential algebra normal form (NF) algorithm; for a thorough explanation of the algorithm, see [72]. In essence, the algorithm yields a set of NF coordinates for which the transformed map is greatly simplified and leads to rotational invariance up to the calculation order in the NF space. From this order-by-order transformation, the NF coordinates $\{x, a, y, b\} \rightarrow \{s_1, t_1, s_2, t_2\}$ exhibit circular behaviors that depend only on amplitudes and parameters such as δ :

$$\begin{pmatrix} s_1 \\ t_1 \end{pmatrix}_2 = \begin{pmatrix} \cos\left(\nu_x(r_1, r_2; \delta)\right) & -\sin\left(\nu_x(r_1, r_2; \delta)\right) \\ \sin\left(\nu_x(r_1, r_2; \delta)\right) & \cos\left(\nu_x(r_1, r_2; \delta)\right) \end{pmatrix} \begin{pmatrix} s_1 \\ t_1 \end{pmatrix}_1,$$
(3.62)

where $r_1^2 = s_1^2 + t_1^2$ and $r_2^2 = s_2^2 + t_2^2$ are the squared amplitudes in normal form. Thus, with the NF map and a straightforward computation of, say, the arc cosine within the DA framework, the full tunes are expressed as Taylor expansions up to the order of the original map:

$$\nu_{x} = \sum_{i,j,k=0} \left(\nu_{x} | r_{1}^{i} r_{2}^{j} \delta^{k} \right) r_{1}^{i} r_{2}^{j} \delta^{k},$$

$$\nu_{y} = \sum_{i,j,k=0} \left(\nu_{x} | r_{1}^{i} r_{2}^{j} \delta^{k} \right) r_{1}^{i} r_{2}^{j} \delta^{k}.$$
(3.63)

For example, nominal tunes from the linear, origin-preserving maps correspond to the $(\nu_{x,y}|1)$ terms and linear chromaticities are naturally calculated from $\xi_{x,y} = (\nu_{x,y}|\delta)$.

A caveat of the rotational invariance in Eq. (3.62) emerges for systems near the effects of resonances. For these cases, the NF algorithm cannot remove some nonlinear map components, and a direct computation of amplitude-dependent tune shifts is not possible. As such, amplitudes of rays under the effects of the resonance-driven terms are not constant and, thus, tunes can evolve over the motion in phase space, losing their physical meaning; however, their limiting average would correspond to the formal definition of a tune as in regular phase space. An important consequence is amplitude modulations that increase muon loss rates in the muon g-2 experiment, as described in Sec. 3.4.2 and 3.4.3.

A thorough investigation of momentum- and amplitude-dependent tune shifts for the muon g-2 storage ring is reported in [90]. Of special importance on nonlinear detuning is the 20 pole from the ESQ electrostatic potential. Its presence in the storage region is manifested in the amplitude-dependent tune shifts as shown in Figs. 3.26 and 3.27 (for $\delta = 0$).

The shift scaling grows in an 8th-power fashion from the closed orbit toward the limiting apertures, as a consequence of the electric 20 pole [90]. On the other hand, magnetic field imperfections do not contribute noticeably to tune shifts, as indicated in the figures.

In the momentum-dependent case $(r_{1,2} = 0)$, tune shifts are mostly proportional to the linear chromaticities for $|\delta| < 0.2\%$ (see Fig. 3.28). Beyond that region and within the momentum acceptance, tunes experience shifts of $\sim 4 \times 10^{-3}$, being negative in the vertical case. The ppm-level magnetic field errors do not contribute noticeably to momentumdependent tune shifts.

In reality, muons with the same betatron amplitudes but separated in momentum (see Eq. (3.58) for a good approximation) scan different regions of the storage volume and, consequently, different field nonlinearities. Thus, momentum- and amplitude-dependent tune shifts have to be treated simultaneously as indicated by $\delta - r_i$ crossed terms in Table 3.3.

Particle-by-particle tune spreading in accelerator machines can lead to beam de-coherence [91]. The g-2 ring is not an exception. Beam tracking simulations with the COSY-based model indicate a strong influence of nonlinearities on the beam de-coherence of the coherent

Figure 3.26: Amplitude-dependent tune shifts ($\delta = 0$) within the storage region without magnetic field imperfections (HV= 18.3 kV). The horizontal axis corresponds to radial betatron amplitudes and the vertical axis represents vertical amplitudes.

Figure 3.27: Amplitude-dependent tune shifts ($\delta = 0$) within the storage region with magnetic field imperfections (HV= 18.3 kV). The horizontal axis corresponds to radial betatron amplitudes and the vertical axis represents vertical amplitudes.

Figure 3.28: Momentum-dependent tune shifts (no betatron amplitudes) with and without magnetic field imperfections (HV= 18.3 kV). Nonlinear shifts take place for $|\delta| > 0.2\%$, inside the momentum acceptance.

betatron oscillation (CBO). Furthermore, toy Monte Carlo simulations [92, 93] with only COSY-based tune shifts are capable of reproducing the observed beam de-coherence. As an example, by taking momentum- and amplitude-dependent tunes in Table 3.3 (up to order 10) with momentum and amplitude $\delta\nu$'s independently and scaled, and reproducing a simulated linear motion as in Eq. (3.58), the radial de-coherence recorded by the g-2 straw tracking detectors is closely recreated (see Fig. 3.29). Without tune shifts, the beam still reduces its initial CBO due to the longitudinal recombination between high- and low-momentum muons, as shown in Fig. 3.47. However, without the nonlinear detuning, observations are not reproduced. At the end of the measurement period (\sim 700 µs after beam injection), a CBO amplitude remanent of about 1 mm might survive as suggested by these simulations extended in time (see Fig. 3.47). Also, Fig. 3.47 suggests small re-coherence pulsations might manifest but to a low extent.

Radial tune

Vertical tune

3.4.2Betatron resonances

When the transverse motion of muons couples with the periodicity of local forces in the storage ring, their betatron oscillation amplitudes may rapidly diverge from the storage volume defined by the collimators, or more commonly experience turn by turn amplitude modulations in a way that they end up hitting the collimators during data taking [69]. Such muons, commonly known as *lost muons* within the muon g-2 collaboration, give up energy to the material they interact with (see Sec. 3.2.4), moving inward and whose daughter positrons escape from detection; in Sec. 3.4.3 the impact of such muons on the ω_a measurement is explained. The electrostatic scraping right after beam injection is crucial for removing

Figure 3.29: Beam radial de-coherence with (left) and without (right) tune shifts at the readout location of the straw tracking detector (station 12). As a reference, data from the tracker is shown in red. The two plots on top display radial beam centroids, whereas the bottom plots correspond to radial beam widths.

muons with large betatron amplitudes. However, even muons with initially small betatron amplitudes around unstable motion regions and nonlinear fixed points in phase-space could become lost at later times under the modulation effects close to resonant conditions.

High-statistical numerical studies of muon loss rates were performed with the COSYbased model to unveil the set of ESQ operating points where significant betatron resonances occur. In Fig. 3.30, simulation results for several high-voltage values applied to the ESQ are presented. The figure shows the fraction of lost muons during the time interval $121 - 186 \,\mu s$

Figure 3.30: Fraction of muon losses between $121 - 186 \,\mu s$ after beam injection with the COSY-based model for several ESQ configurations. Measurements [94]—shown in arbitrary units—result from detections of minimum ionizing particles that deposit ~ 170 MeV of energy in two adjacent calorimeters while two collimators were inserted to the storage region.

after beam injection. Vertical error bars correspond to the standard error of the multiple simulations executed in parallel that were necessary to surpass the resolution required and clearly distinguish resonance peaks (i.e., $\sim 6.8 \times 10^6$ muons at beam injection).

Due to the sensitivity of E989, even the relatively small effects of high-order resonance conditions are avoided. To describe the interplay between the field imperfections in the storage ring and the resonant conditions, the ring is idealized as a superposition of a uniform vertical magnetic field and electric quadrupole fields coming from the ESQ, where all the extra field from the ESQ design and magnetic field imperfections are treated as perturbations to the linear case. In particular, for simplicity this model assumes a smooth behavior of the unperturbed betatron oscillations that does resemble the real case [95]:

$$x(\theta) \approx H\cos(2\pi\nu_x\theta + \phi_x), \quad y(\theta) \approx V\cos(2\pi\nu_y\theta + \phi_y)$$
 (3.64)

where θ is the azimuth, and H and V are constant radial and vertical betatron amplitudes (a

good approximation in the weakly focused g-2 stored muon beam), respectively. Considering both magnetic and electric potentials in the form

$$\Phi(x, y, \theta) = \sum_{l=0}^{\infty} \sum_{m=0}^{\infty} \sum_{N=0}^{\infty} C_{l,m,N} x^l y^m \cos(N\theta + \phi_{lmN}), \qquad (3.65)$$

Eqs. (3.64) and (3.65) can be combined to estimate the transversal forces in terms of 2k-pole terms (k = l + m) and Nth azimuthal harmonics. The leading terms from Fourier analysis of the perturbations yield the following conditions that resonate with the betatron motion:

$$(l-1)\nu_x \pm m\nu_y \pm N = \Lambda, \quad l\nu_x \pm (m-1)\nu_y \pm N = \Lambda \tag{3.66}$$

where $\Lambda = \pm \nu_{x,y}$ depending on the field that drives the resonance. In general, vertical forces induce more muon losses than horizontal forces due to the relatively smaller vertical admittance of the ring (see Sec. 3.5.1). The storage ring fields are mostly four-fold symmetric, thus favoring N = 0, 4, 8, ... Figure 3.31 depicts resonance lines as well as the operating setpoints of the storage ring. Resonant tune lines up to k = 10 are shown, which are sufficient for our purposes of covering all the main multipole terms that are implemented in the COSY-based ring model, including the ESQ 20 pole.

Along with the resonance conditions shown in Fig. 3.31, the observed resonances in the storage ring depend on the angle advancement spread in phase-space, betatron amplitudes, momentum deviations, and initial phase of muons revolving the storage ring. The combination of these properties dictates how frequently a muon crosses unstable conditions in phase-space to experience resonant effects or not. For instance, the continual growth of resonance peak widths for increasing HV observed in Fig. 3.30 relates to the vertical angle

Figure 3.31: An illustration of resonant tune lines and operating points (i.e., ESQ nominal voltages) of the g-2 storage ring. The high-voltage applied to the ESQ plates to set operating points are shown next to resonances predicted by numerical studies with the COSY-based ring model. Measurements of lost muons have revealed resonance peaks at $\sim 13.1, 16.8, 18.6, \text{and } 21.1 \text{ kV}$ as well (see Fig. 3.30). Lost muons measurements have not been performed for higher ESQ voltages. Red markers show the operating points used in Run-1.

advancement spread. It is worth noting that this angle, which can be defined as the turnby-turn angular evolution of the muon coordinates in vertical phase-space at an arbitrary azimuth location, advances in a more periodic manner as the vertical betatron function of the storage ring, β_y , significantly decreases on average for higher voltages within the explored HV range. Regarding betatron amplitudes and momenta, these properties, which are unique to each muon within the stored beam, indirectly define the attributes of the peaks presented in Fig. 3.30 as well, since resonance conditions in Eq. (3.66) are not uniquely satisfied by all the stored muons due to nonlinear tune shifts in the g-2 storage ring. The tune footprint for HV= 18.3 kV (used in Runs 1a and 1d) in Figure 3.32 illustrates this effect. Even though the operational setpoint is not at resonance, it is close enough to the $3\nu_y = 1$ resonant condition so that momentum- and amplitude-dependent tune shifts push muons to the resonance region.

To minimize systematic errors due to muon losses, the storage ring must run at operating points sufficiently away from betatron resonances. As shown in Fig. 3.31, the system falls into resonance around specific setpoints and not at every intersection with resonant tune lines. This feature is mostly due to the rather specific set of nonlinear electrostatic multipoles provided by the 4-fold symmetric ESQ, where the 20 pole has the largest strength. In addition, the reinforcement of multiple resonant conditions is also a main determinant of the observed and measured betatron resonances, which can be noticed in their proximity to the points where several resonance conditions converge. Nevertheless, even though the multipoles that describe the measured magnetic field imperfections do not favor particular azimuthal harmonics due to their somewhat random distribution along the ring azimuth, they still have an important effect on betatron resonances, as shown next.

Figure 3.32: With the tune shifts readily available from the COSY-model, momentum and normal form radii of stored muons from a realistic initial distribution as described in Sec. 3.2.5 are used for the calculation of the tune footprint. The ESQ setpoint is 18.3 kV. Due to nonlinear amplitude- and momentum-tune shifts, a considerable fraction of the stored muons is affected by the resonance around in tune space, especially the $3\nu_y = 1$ resonant condition driven by the skew magnetic sextupole term. Red(blue) markers indicate high(low) density of entries in the tune footprint.

Resonance Driving Terms

A deep understanding of the forces that drive betatron resonances is tantamount to a detailed characterization of the conditions in the storage ring that excite muon loss rates. By identifying all the resonances that emerge from the imperfections of the ring already known (i.e., nonlinear electric perturbations contributed by the ESQ and magnetic field inhomogeneities from NMR probes measurements), it is possible to address the origin of resonant peaks from lost muons measurements not accounted for in the COSY-based model. Extra peaks could be generated by mis-powering or misalignments of the ESQ plates, transient magnetic fields outside the bandwidth of the NMR probes, and other factors not included in the symplectic tracking simulations that otherwise would be difficult to evaluate and would also directly affect the evolution of ω_a under momentum-spin correlations.

In addition, modifications to the default settings of the simulated ring model permit determining the driving terms that generate each betatron resonance peak. In Fig. 3.33, simulation results are shown for the following modifications to the original ring model configuration (see marker legend in Fig. 3.33 for each case):

- (i) All E-multipoles, B-field inhomogeneities ON (original case, red)
- (ii) Only 4th E-multipole, B-field inhomogeneities ON (gold)
- (iii) No 20th E-multipole, B-field inhomogeneities ON (magenta)
- (iv) All E-multipoles, B-field inhomogeneities OFF (blue)
- (v) Only 4th and 20th E-multipoles, B-field inhomogeneities OFF (green)
- (vi) No 20th E-multipole, B-field inhomogeneities OFF (orange).

The 2D multipole fits to the magnetic field NMR measurements (abbreviated as "Bfield inhomogeneities" in the list above) introduce lost muon fractions of ~ $6 \times 10^{-4}/\gamma \tau_{\mu}$ even at operating points away from the main betatron excitations. Betatron resonance peaks observed from measurements and/or simulations can be explained from resonance

Figure 3.33: Fraction of muon losses from simulations during the time interval $121 - 186\mu$ s after beam injection. Configuration details are listed on page 116. The bottom figure depicts lost muon fractions with a reduced vertical range to discern losses when magnetic field imperfections are not accounted for.

conditions (Eq. (3.66)), which can be independently driven by one or several electric and magnetic high-order multipoles in the storage ring model (see Table 3.4).

HV[kV]	$a\nu_x + b\nu_y = c$	
13.1	$3\nu_x + 4\nu_y = 4$	
16.8	$\nu_x - 3\nu_y = 0$	
18.6	$3\nu_y = 1$	
21.1	$2\nu_x + 6\nu_y = 4$	
24.7	$\nu_x + 8\nu_y = 4$	
30.4	$3\nu_x + 3\nu_y = 4$	

Table 3.4: Resonant conditions related to betatron excitations.

Nevertheless, Fig. 3.33 shows the interplay between magnetic(electric) nonlinearities and electric(magnetic) resonances. For instance, for a ring with $HV \sim 13.1$ kV the resonance driven by the electric 20-pole terms derived from the curvature of the plates is boosted by lower order nonlinearities from the imperfect magnetic field; several resonant tune lines near such an operating point reinforce the resonance. However, by analyzing the high-order terms of the storage ring transfer map in Normal Form (NF) it is possible to understand with more detail the role of nonlinearities in relation to resonances.

For $HV \sim 16.8$ kV, either the magnetic or electric guide fields can drive the resonance condition $\nu_x - 3\nu_y = 0$. The magnetic forces build up a larger resonance than the electric case, as found in simulations. In the electric case, electrostatic potential coefficients from the 20 pole are needed to see a resonance. On the other hand, the magnetic octupole can drive the resonance through vertical forces from horizontal magnetic fields proportional to $B_x \propto xy^2$. Azimuthal independence of the electric/magnetic potential (i.e., N = 0) is favored for this resonance.

The $HV \sim 18.6$ kV resonance deserves particular attention [96–98] as it is near enough the ESQ operational setpoints during Runs 1a and 1d (i.e., 18.3 kV). Simulations with the COSY-

Figure 3.34: On the left, magnetic skew sextupole coefficient a_2 as measured by NMR probes. On the right plot, Fourier decomposition of the coefficient a_2 in azimuthal harmonics $a_2 = \sum_{N=0}^{n} a_{2,N} \cos (N\theta + \phi_N)$. The N = 1 term, which is the main driver of the resonant condition $3\nu_y = 1$, is depicted in green color.

based model indicate that the resonance is purely driven by magnetic field inhomogeneities, though a reciprocity between resonances and nonlinearities from different origin—electric or magnetic—exists. The driving force behind this vertical resonance is the radial magnetic field

$$\Delta B_x(x, y, \theta) = -B_0 a_{2,N=1} \cos(\theta + \theta_1) y^2, \qquad (3.67)$$

The coefficient $a_{2,N=1}$ is the first azimuthal harmonic of the magnetic skew sextupole; a fast Fourier transformation (FFT) of the measured a_2 in Fig. 3.34 (right plot) shows a non-zero N = 1 component, sufficiently large to drive a nonlinear betatron resonance as depicted in Fig. 3.35.

The effect of the $3\nu_y = 1$ resonance extends all the way to the Run-1 ESQ setpoint HV = 18.3 kV due to amplitude- and momentum-dependent tune shifts. By turning on and off the skew sextupole component of the magnetic field implementation in the COSY-based model [98], it was demonstrated that in the absence of a_2 the betatron resonance peak at $HV \approx 18.6 \text{ kV}$ does not build up. Moreover, it was also found that by reducing the most

Figure 3.35: Lost muons fraction over a muon lifetime after the scraping stage is completed. In red (triangular markers), all the magnetic multipole terms are turned on during the beam tracking simulation, whereas in blue (diamond markers), these are turned off. In subsequent simulations, it was found that only the magnetic skew sextupole term from measured field inhomogeneities was sufficient to drive the betatron-resonance peak at $HV \approx 18.6$ kV.

prominent peak of the skew sextupole component around the azimuth noticeably reduces $a_{2,N=1}$ and, consequently, the resonance effect. However, it might be more practical to configure the ESQ setpoint away from $HV \approx 18.6 \,\mathrm{kV}$ rather than smoothing out the skew sextupole magnetic field inhomogeneities with active shimming, but it depends on the specific operational circumstances. The impact of equivalent electric skew sextupole coefficients from ESQ plate misalignments was also analyzed. Qualitatively, the sharpness of the observed muon loss rate resonance at $HV \approx 18.6 \,\mathrm{kV}$ was not reproduced in this scenario. And quantitatively, the misalignment configuration necessary to recreate a discernible resonance peak was unrealistic based on subsequent misalignment surveys [99]. Thus, it was concluded that the magnetic skew sextupole was the main driving force of the $3\nu_y = 1$ resonance.

3.4.3 Lost muon mechanisms

For a stored beam with momentum-phase correlations at injection time, muons that permanently escape from the storage volume during data taking (and whose decay positrons are not detected by the calorimeters) can potentially bias the measured ω_a by inducing slow drifts in the phase in Eq. (1.25). Since the Beam Delivery System (BDS) delivers a muon beam with a correlation between the g-2 phase and momentum of about 10 mrad per $\Delta \delta = 0.01$ (Sec. 2.3.4), a reduction of these so-called *lost muons* is tantamount to a mitigation in ω_a systematic errors.

By tracking symplectically the muon beam with the COSY-based model for n = 1 and n = 10 order transfer maps, a detailed picture of the mechanisms that drive muons to be lost can be developed. Externally to the work presented in this document, several mechanisms that potentially drive muon loss have been studied (for details, see [100]), among them muon scattering with the residual vacuum in the storage region, transient electromagnetic fields, and nonlinear fields away from resonances. In the analysis, it was also determined that the main reason there are lost muons during production measurements in the linear regime is the scraping method implemented after beam injection; a small fraction of muons beyond the limiting apertures of the storage region (i.e., $\sqrt{x^2 + y^2} > 45$ mm at collimator locations) can revolve the ring for thousands of turns before a direct collision with a collimator. Linear simulations are able to reproduce the muon loss rates shown in Fig. 3.30 away from betatron resonances [100].

At HV= 18.3 kV (the setpoint used in Runs 1a and 2d, and next to the ESQ voltage HV= 18.2 kV used in posterior g-2 runs), nonlinear resonances driven by the $3\nu_y = 1$ condition play a significant role in muon loss rates. As shown next, under the Run-1 injection settings

nonlinear loss rates contribute to considerably higher muon loss rates than linearly driven losses.

It is helpful to start with a muon that does not get lost in the linear regime and take its motion as a reference, where HV = 18.3 kV. In the stroboscopic view (i.e., at one azimuthal location), such muon follows well-defined elliptical motion in radial/vertical phase space as indicated by Eq. (3.58) and expected from Liouville's theorem. Also, its radii in normal form coordinates are invariant. Figure 3.36 illustrates the motion in this case. Consequently, the

Figure 3.36: Phase space coordinates and maximum excursion of a muon not lost (reference case).

maximum transverse excursion r_0 relative to the ideal orbit can be described as

$$r_{max} = \sqrt{(A_x + |D_x\delta + x_0|)^2 + (A_y + |y_0|)^2}.$$
(3.68)

In fact, this dynamical evolution is also expected in the nonlinear regime only when there are no resonance-driven terms that could affect the pursued rotational invariance of a normal form transformation (see Eq. (3.62)).

Lost muons also emerge in COSY-based linear simulations. Even though a muon beam with data-driven initial conditions at $4 \,\mu s$ (see Sec. 3.6.3) and initially cleaned via conven-

tional scraping (see Sec. 3.2.1) is tracked down, alas, about 0.2% of the stored muons at $t > 30 \,\mu\text{s}$ with $r_{max} > r_0$ are not removed from the beam. Figure 3.37 shows a typical sample of these muons and Fig. 3.38 their maximum excursions, which confirm their survival for several microseconds inside the data-taking time range. High-order resonances

Figure 3.37: Trajectories in phase space of three different muons (distinguished by color) in the linear regime.

are irrelevant in the linear regime, and as a consequence linear chromaticities are the only contributors to small tune shifts, given the constrained momentum acceptance of $\delta \sim 0.55 \%$ (see Fig. 3.39).⁵

Now the attention is turned to the case where nonlinear motion is accounted for. The same initial muon distribution and scraping scheme are used as in the linear simulations

 $^{^{5}}$ In this subsection, the meaning of color coding is shared in figures.

Figure 3.38: Maximum excursions of three lost muons in the linear regime.

described above. However, the symplectic condition is enforced via a symplectic transformation of the transfer map as described in [70]. In this manner, the Jacobian of the map is equal to one, and consequently the phase space volume is conserved turn by turn, an essential characteristic of Hamiltonian motion.

Figure 3.40 shows phase space in regular coordinates of three muons lost in the nonlinear, symplectic simulations. The radial motion is not influenced by resonance terms, in agreement with the $3\nu_y = 1$ vertical resonance driven by skew sextupole terms of the magnetic field. On the other hand, vertical amplitude modulations manifest and, as a result, maximum excursions evolve over time (see Fig. 3.41). In the linear mechanism, the statistics involved in the time it takes a muon with $r_{max} > r_0$ is plain. The higher r_{max} is, the faster the muon is lost (loss rates can be derived from Eq. (3.58)). On the other hand, muons nonlinearly modulated whose maximum excursions intermittently visit values beyond collimation apertures survive for longer periods, as indicated by linear versus nonlinear muon loss simulation comparisons (see Fig. 3.43).

When the shifted tunes of nonlinearly driven lost muons are extracted as explained in

Figure 3.39: Tunes of three lost muons in the linear regime. Note the proximity between the red and black entries (the red marker partially covers the marker in black color).

Sec. 3.4.1, all their coordinates in tune space fall within the vicinity of the $3\nu_y = 1$ resonance as shown in Fig. 3.42; as they move around unstable and stable 3-period fixed points in phase space [101], tunes constantly shift in conjunction with vertical betatron amplitudes in phase space.⁶ The period-3 fixed point structures are clearly visible from muon symplectic tracking within the storage region and momentum acceptance, as shown in Fig. 3.44. Vertical betatron amplitudes are modulated as muons move in phase space around the stable and unstable fixed points generated by the $3\nu_y = 1$ nonlinear resonance. Although the motion is

 $^{^{6}}$ Animated examples of lost muon shifting tunes can be found in [102].

Figure 3.40: Trajectories in phase space of three different muons (distinguished by color) in the nonlinear regime.

stable, modulations interfere with the time it takes for a muon to become lost.

Further studies summarized in Fig. 3.45 were aimed at understanding the multi-dimensional nature of muon loss rates. Using an initial distribution based on straw trackers Run-1a data and the scraping scheme used during Run-1, it is concluded that muon loss rates are characterized not only by resonance-driven effects but by the number of inserted collimators. In the presented results regarding muon loss driving mechanisms, two collimators were inserted (downstream of ESQ stations Q3L and Q4S) as in Run-1 during tracking simulations. For posterior runs, all collimators are inserted, for which case muon loss rates are substantially reduced as suggested by the COSY-based model simulations. However, another factor to account for is the beam injection quality which determines the number of outermost muons

Figure 3.41: Maximum excursions of three lost muons in the nonlinear regime.

likely to get lost. In addition, Fig. 3.45 also displays a comparison with and without the effect of the time-evolving ESQ fields during Run-1d (see Sec 3.6), indicating higher a muon loss fraction in the former case as the nominal tune moves toward the $3\nu_y = 1$ resonance and the vertical beam centroid drifts over the data taking period. More important for a reliable analysis of lost muons is the symplectic transformation for tracking; in its absence, an overall emittance growth is observed in simulation results, consequently producing an artificial muon loss fraction increase (see Fig. 3.45).

3.5 Nominal Characteristics of the Stored Beam

Under normal circumstances, the beam delivery and injection process into the g-2 storage ring at Fermilab, as well as the electric/magnetic lattice inside the ring, specify the temporal and azimuthal behavior of the muon beam. Due to the beam transverse profile being mismatched with the ring optical settings (especially in radial phase space), transverse os-

Figure 3.42: Tunes of three muons in the nonlinear regime before getting lost.

cillations of the beam centroids and widths are common.⁷ On the azimuthal side, beam centroids typically follow mm-level closed orbits and beam radial/vertical widths are modulated by the variations of the optical lattice (of about 0.4 mm along the ring azimuth) in an almost four-fold symmetric pattern. By tracking down a realistic beam—whose initial conditions are prepared based on Run-1a beam data (see Sec. 3.6.3)—with the COSY-based model under nominal settings at $HV=18.3 \, kV$ (and magnetic fields as measured around Run-1a), representative samples of the beam over time and azimuth are presented in this

⁷At the time of this dissertation, advanced RF techniques to substitute conventional ESQ scraping were being developed by Muon g-2 collaborators to mitigate beam beating [103].

Figure 3.43: Muon loss fractions with nonlinearities (black curve) and without them (gray curve) from symplectic tracking, COSY-based, beam simulations. The ESQ setpoint was 18.3 kV, two collimators were inserted, and both cases start with the same data-based initial distribution. Muon loss rates are highly affected by nonlinearities of the guide fields.

Figure 3.44: Stroboscopic tracking in the vertical phase space illustrating orbit behavior with two period-3 fixed point structures present [101], for ESQ voltage at 18.3 kV. Trajectories in blue and green colors are examples of muons (within the ring admittance and momentum acceptance) with highly modulated vertical amplitudes. Picture by courtesy of Adrian Weisskopf.

Figure 3.45: Muon loss rates from several tracking simulations (HV=18.3 kV). The effect of damaged resistors and the effect from symplectic enforcement during tracking is shown.

section. Several experimental improvements were made after Run-1 concluded, where the radial CBO amplitudes were reduced and momentum spread became better centered, reducing in this way dispersive effects. However, the main features discussed in this section are always expected to an observational level.

The results presented next serve to characterize the transverse frequencies of the muon beam and validate the implementation of optical lattice functions—as well as a distinction of their limitations—to describe the transverse beam intensity around the azimuth of the storage ring. These validations are important since the optical lattice functions from the COSY-based model are extensively used for ω_a systematic corrections (i.e., pitch [104], phase acceptance [44], and Run-1 E-field [105] corrections) and the muon weighting of the magnetic field \tilde{B} [106].

First, it is useful to specify the boundaries of the stored muon beam. And at the end of the section, the initial momentum-time correlation of the beam in the muon g-2 experiment obtained from these studies was used to discover and estimate the largest systematic uncertainty of the E-field correction.

Figure 3.46: Qualitative comparison between stored muon rates from simulations (gray) at $t = 186 \,\mu\text{s}$ after beam injection and measured relative positron rates (arbitrary units) from stored muon decays [107]. Error bars correspond to standard errors of the multiple numerical analyses for each ESQ voltage configuration. As the vertical and radial admittances increase and decrease, respectively, proportional to the ESQ voltage, the fraction of stored muons increases, reaching a plateau at 22 kV where the stored fraction starts to become more sensitive to the radial admittance. The low fraction of stored muons is a consequence of the momentum spread being about two times larger than the momentum acceptance, the dispersion mismatch between the end of the M5-line and the storage ring, and the imperfect kicks purposed to inject the beam.

3.5.1 Beam boundaries

The $r_0 = 45 \text{ mm}$ radius aperture of inserted collimators together with the optical lattice of the ring define the largest transverse emittance (known as admittance) and momentum acceptance in the storage ring. From these bound parameters, the maximum betatron amplitudes, maximum angles a and b, and limiting momentum can be established along the azimuth. Furthermore, the stored muons fraction is also affected by these quantities, as shown in Fig. 3.46.

By finding the largest beta functions at collimator locations and using Eq. (3.55), admit-

tances are defined as

$$\varepsilon_{x,y}^{max} = \frac{r_0^2}{\beta_{x,y}^{max}}.$$
(3.69)

For Run-1 datasets, their nominal values are shown in Table 3.5. It is worth highlighting the role of the magnetic field in the larger radial admittance.

HV [kV]	$\varepsilon_x^{max}[\pi \text{mm.mrad}]$	$\varepsilon_y^{max}[\pi \text{mm.mrad}]$
18.3	268.757	92.8262
20.4	266.946	97.8427

Table 3.5: Storage ring nominal admittances for Run-1 ESQ setpoints.

The collimator geometry is circular and not squared; thus, admittance values as shown in Table 3.5 would correspond to a beam with very low intensity.

Maximum angles are obtained via

$$a_{max}(\theta) = \sqrt{\varepsilon_x^{max} \gamma_x(\theta)} \quad , \quad b_{max}(\theta) = \sqrt{\varepsilon_y^{max} \gamma_y(\theta)}$$
(3.70)

and maximum betatron amplitudes are given by

$$x_{max}(\theta) = \sqrt{\varepsilon_x^{max}\beta_x(\theta)} \quad , \quad y_{max}(\theta) = \sqrt{\varepsilon_y^{max}\beta_y(\theta)}$$
(3.71)

For a numerical reference see Table 3.6, which displays the small variations thanks to the relatively weak focusing scheme.

Table 3.6: Maximum value ranges in the storage ring along the azimuth for Run-1 settings.

HV [kV]	$x_{max} \; [mm]$	a_{max} [mrad]	$y_{max} \; [mm]$	$b_{max} \text{ [mrad]}$
18.3	$\{44.46, 45.41\}$	$\{5.91, 6.04\}$	$\{44.27, 45.10\}$	$\{2.06, 2.10\}$
20.4	$\{44.42, 45.57\}$	$\{5.86, 6.01\}$	$\{44.18, 45.12\}$	$\{2.17, 2.21\}$

The momentum acceptance is also directly calculated in the optical view, where the maximum radial dispersion at collimator locations is taken, which yields

$$\delta_{max,min} = \pm \frac{r_0}{D_x^{max}} \approx \pm 0.56 \%. \tag{3.72}$$

3.5.2 Temporal motion of the beam

The optical configuration at the end of the M5 beamline is meant to focus the beam horizontally for its passage through the backleg hole in the ring, which houses the $18 \text{ mm} \times 56 \text{ mm}$ (horizontal and vertical dimensions, respectively) superconducting inflector meant to cancels out the surrounding magnetic field. The outcome of this process is a beam whose α , β , and γ functions do not correspond to the optical lattice functions of the ring. Also, the radial dispersion prior to the storage ring entrance is close to zero; thus, stored muons will follow different momentum-dependent radial closed orbits with an overall coherence due to the injection favoring the storage of specific betatron phases. All these features lead to a mismatched beam.

As indicated by Eq. (3.58), the nonzero averaged betatron amplitudes give place to oscillations of the beam centroids and widths over time. Figures 3.47 and 3.48 depict such temporal behavior as seen at one azimuth of the ring from COSY-based simulations. As explained in Sec. 3.4.1, nonlinear tune shifts and (to a lower extent) the recombination of high- and low-momentum muons yield the de-coherence of the temporal modulations, which are expected to have amplitudes of less than a millimeter by the end of each fill ($\sim 700 \,\mu$ s). The beam-ring mismatching is less severe in the vertical phase space than in the radial case thanks to the negligible vertical dispersion and more comparable beam-ring optical functions.

Figure 3.47: Long-term radial beam de-coherence.

Fast Fourier transforms (FFT), shown in Figs. 3.49 and 3.50, reveal the typical transverse frequencies of the stored beam. Since in this stroboscopic perspective the beam is observed at one location, its frequencies are combinations of cyclotron and radial/vertical frequencies, listed in Table 3.7.

Table 3.7: Transverse motion frequencies of the g-2 stored beam (HV= 18.3 kV). The last column indicates cyclotron revolutions per frequency cycle.

Frequency (f)	Expression	[MHz]	$[\mathrm{rad}/\mu\mathrm{s}]$	Period [µs]	Cyclotron revs.
f_c	$p_0/(2\pi m_\mu \gamma_0 \rho_0)$	6.7050	42.128	0.14914	1.0000
f_X	$f_c u_x$	6.3326	39.789	0.15791	1.0588
$f_{\text{CBO},x}$	$f_c \left(1 - \nu_x\right)$	0.37238	2.3397	2.6855	18.006
f_y	$f_c \nu_y$	2.21810	13.937	0.45084	3.0228
$f_{\text{CBO},y}$	$f_c \left(1 - \nu_y\right)$	4.4869	28.192	0.22287	1.4943

In Sec. 3.3, the concepts of closed orbits and optical lattice functions were elaborated in the context of the g-2 storage ring. In this way, a description of a matched beam is expected to be exact in the linear regime. At this point where nonlinearities and beam mismatch are sufficiently quantified, the beam-to-ring relations that emerge in this framework (i.e.,

Figure 3.48: Long-term vertical beam temporal modulations.

Eqs. (3.53) and (3.57)) are tested.

In the temporal dimension, beam centroids and widths at azimuthal locations are tracked from symplectic and nonlinear simulations, and the closed orbits and optical lattice functions are calculated with the COSY-based model. Figures 3.51 and 3.52 display results at 157° downstream from the entrance of ESQ station Q1S. An electric field at ESQ station Q1L with the time dependence expected during Run-1a (see Sec. 3.6.1) is also accounted for in these tracking-vs-lattice comparisons in order to test the framework beyond its nominal conditions. Random time offsets of the size of oscillation periods shown in Table 3.7 are applied to temporal coordinates from simulation results in order to wash out frequencies from beam mismatching and directly compare beam drifts over the whole data taking period. Such drifts are the relevant quantity to pay attention to since they can potentially bias the ω_a measurement; in general, effects from oscillations driven by beam mismatch cancel out.

Beam centroids do follow closed orbits as indicated in Eq. (3.57) and shown in Fig. 3.51; the beam centroid oscillates with the closed orbit as the equilibrium fixed point. Beam

Figure 3.49: Beam frequencies extracted with FFT from centroids motion.

Figure 3.50: Beam frequencies extracted with FFT from widths motion.

widths, on the other hand, require a less straightforward extraction from the lattice side. In the radial case, the momentum spread σ_{δ} is required to calculate the dispersive effect on the radial width. In addition, emittances are also necessary to be known. In the experiment, emittances and the momentum beam distributions are obtained externally from FR analysis [51] and straw tracker data; in tracking simulations, these quantities are directly obtained. Figure 3.52 shows how the vertical width is well described by Eq. (3.53) when the timeevolving vertical emittance is taken into account (see Fig. 3.53). However, the description of the radial width in the temporal dimension from Eq. (3.53) is off by a scale factor of

Figure 3.51: Comparison between closed orbit and beam centroid from tracking at 157° downstream from the entrance of Q1S. Tracking data is randomized to remove beam beating from mismatch. The initial distribution and guide fields are prepared for the 60*h* case as explained in Sec. 3.6.

Figure 3.52: Comparison between beam width from optical lattice functions (green and red entries) and beam width from tracking at 157° downstream from the entrance of Q1S. The differences are discussed in the main text. Tracking data is randomized to remove beam beating from mismatch. The initial distribution and guide fields are prepared for the Run-1a case as explained in Sec. 3.6. The red line corresponds to a case with constant emittances, which in the vertical case plays a role in describing accurately vertical beam widths.

Figure 3.53: Beam emittances from tracking. Due to the smaller vertical admittance, the vertical emittance is more affected by muon loss rates.

about 1.07. This discrepancy originates from the skewness of the radial (and mismatched) distribution, which deviates from the postulate of having elliptical distributions in phase space (or, equivalently, normal distributions per dimension). Nevertheless, the scale factor is constant and the time evolution is captured by Eq. (3.53). Figures 3.54 and 3.55 show from the simulation side the phase space in both transverse directions, as well as their spatial projections (note skewed radial distribution).

3.5.3 Beam azimuthal modulation

The precise reconstruction of muon coordinates from the straw tracking detector measurements provides reliable time-dependent transverse muon beam intensity profiles. On the other hand, the two tracking detector stations are limited to their narrow sensitivity of about 5°, $\sim 1 \,\mathrm{m}$ upstream from their azimuthal locations (see Fig. 1.11). All things considered, the 24 calorimeters around the inner side of the ring could ideally be used to measure the muon beam along the azimuth. However, these detectors were specifically designed to

Figure 3.54: Radial phase space at late times of the data taking period (left) and its spatial projection (right) from Run-1 simulation. The pattern closely resembles observations and its characteristic skewness is present in all Run-1 datasets.

measure positrons energy and arrival time (see Sec. 1.2.2); a trustworthy reconstruction of the muon beam transverse profile out of detected positrons that hit calorimeter crystals is therefore difficult due to acceptance, resolution, and material effects as positrons travel through the ring instrumentation.

For this purpose, the COSY-based model provides optical lattice functions—verified with reliable tracking simulations—in order to extrapolate straw tracker transverse beam data around the ring. The resulting extrapolation is used to quantify systematic errors from the pitch, electric, and phase acceptance corrections to ω_a . It is also utilized to average the magnetic field with the muon beam around the ring for the calculation of \tilde{B} in Eq. (1.30). Using optical lattice functions is more advantageous than beam tracking simulations since it is not subject to frequencies from beam mismatch nor features of the tracking simulation (e.g., symplecticity and computational time). Once detailed modeling of the guide fields (under normal or unexpected scenarios as during Run-1) in the storage ring is implemented, optical lattice functions are reproduced on a case-by-case basis. Furthermore, it has been

Figure 3.55: Vertical phase space at late times of the data taking period (left) and its spatial projection (right) from Run-1 simulation.

shown that a proper transformation of the measured beam with all its features is also possible with the optical lattice functions for the purposes of the experiment analysis.

Based on tests with the COSY-based model, the azimuthal behavior of the beam is indeed reproduced by the optical lattice functions. Since tracker data provides information at two azimuths, an effective radial emittance is calculated via Eq. (3.53), where σ_{δ} is extracted from fast rotation (FR) analysis [51], the measured radial width is taken, and the radial beta and dispersion functions are calculated at tracker locations. In the vertical case, the emittance is simply calculated with vertical width measurements and vertical beta functions from the model. It is necessary to first wash out the beam temporal oscillations with data randomization [108] or averaging measurements within time ranges being multiples to CBO frequencies. Figures 3.56 and 3.57 show the good performance of optical functions for the extraction of the beam azimuthal behavior. Even though the radial distribution is not well behaved, the lattice functions can be safely used within errors of 0.04 mm.

To extrapolate the beam transverse intensity $M(x, y, t; \theta_1) \rightarrow M(x, y, t; \theta_2)$ muon by

Figure 3.56: Comparison between closed orbits (red curves) and randomized beam centroids from Run-1 tracking simulations.

Figure 3.57: Comparison between beam widths from optical lattice functions (red curves) and randomized beam widths from Run-1 tracking simulations.

muon, the following expression is used:

$$x(\theta_2) = \kappa_x(\theta_1, \theta_2) \left(x(\theta_1) - \bar{x}(\theta_1) \right) + x_0(\theta_2) + D_x(\theta_2) \bar{\delta}$$

(3.73)
$$y(\theta_2) = \kappa_y(\theta_1, \theta_2) \left(y(\theta_1) - \bar{y}(\theta_1) \right) + y_0(\theta_2),$$

where

$$\kappa_x(\theta_1, \theta_2) = \frac{\sqrt{\varepsilon_x \beta_x(\theta_2) + D_x^2(\theta_2)\sigma_\delta}}{\sigma_x(\theta_1)} \quad \text{and} \quad \kappa_y(\theta_1, \theta_2) = \sqrt{\frac{\beta_y(\theta_2)}{\beta_y(\theta_1)}}.$$
 (3.74)

In this form, the temporal oscillations as measured are captured. Analysis for the phase

acceptance correction has proved the validity of these transformations with tracker data as input [109]. For the muon weighting of the magnetic field, since the temporal modulations are not relevant, the entire beam distribution integrated over time is shifted and scaled according to Eq. (3.74); see Sec. 4.5 for more details. Pitch [104] and E-field corrections [105] require a more direct use of the COSY-based optical lattice functions.

3.5.4 Time-momentum correlations

As explained in Sec. 1.3.3, a momentum-time correlation after beam injection introduces the largest systematic error of the E-field correction. At the time of this dissertation, no procedure to measure this correlation in the experiment has been established. With the COSY-based model, the initial distribution at the inflector exit (see Sec. 3.2.5) is transferred into the storage ring, whose longitudinal profile (Fig. 3.14) and the injection kickers pattern (Fig. 3.10) determine the initial momentum-time correlation. $4 \,\mu s$ after beam injection, the resulting collimated beam is expected to yield a momentum-time distribution as shown in 3.58 under Run-1a kicker settings (-200, -170, -185G as maximum strengths). Injection of high-momentum muons ahead of the longitudinal center of the beam is favored; such muons require less outward kick to be stored, and the ringing of the kicker pulse benefits the process. The same pattern occurs for high-momentum muons on the other side of the beam, although to a lower extent. Figure 3.59 reveals the characteristic shape of the beam momentum spread from FR analysis, which indicates a proper recreation of the injection process in the COSY-based simulation. Other q-2 collaborators produce similar simulations of the momentum-time distribution [110] and the output is qualitatively equivalent, although the COSY-based simulation exhibits a stronger correlation; collaborative efforts are in process to refine the calculation of the systematic error associated with the momentum-time correlation

Figure 3.58: Typical Run-1 momentum time beam distribution from Run-1 tracking simulation.

Figure 3.59: Projections of the typical Run-1 momentum time beam distribution from Run-1 tracking simulation.

for g-2 runs posterior to Run-1.

3.6 Beam Dynamics of Run-1

During all the four Run-1 datasets (in chronological order 60h (1a), HK (1b), 9d (1c), and EG (1d)), measurements of the transverse muon beam from the straw tracker detectors revealed unexpected drifts of the beam centroid and width over a fraction of the fill [86] (i.e., $t \leq 200 \,\mu\text{s}$ after beam injection). Furthermore, CBO frequencies of the radial centroid oscillations were also found to evolve during the data taking period, slowly converging to their nominal values over the course of a fill.

Under nominal conditions the ESQ stabilizes after $t \approx 30 \,\mu$ s, in which case the guide fields are constant and thus the optical lattice, too. In this normal scenario, CBO frequencies do not change since the stable lattice provides constant betatron tunes (see Table 3.7). Also, closed orbits are expected to be stable and, consequently, the fixed points around which beam centroids oscillate are indeed fixed. As presented in Sec. 3.5.2, transverse emittances are sensitive to muon loss rates as experienced during Run-1; therefore, beam widths could drift under a stable optical lattice. All these expectations served to interpret observations and determine the specific behavior of the optical lattice during Run-1.

In particular, CBO frequencies relate to field gradients, and centroid coordinates result from dipole field steering. Less ambiguously and in the view of 2D multipoles field expansion, normal quadrupole terms strongly relate to the radial CBO frequency via radial tunes and skew dipole terms define long term motion of the vertical beam centroid via vertical closed orbits. Being mindful of such lattice-beam relations, measurements of the radial CBO frequency and vertical beam centroid over the four Run-1 datasets (see Figs. 3.60 and 3.61) are taken as input for the reconstruction of the unmeasured Run-1 ESQ electric fields.

Figure 3.60: Radial CBO frequencies during the four Run-1 datasets from straw tracking detectors data. Semi-transparent markers are obtained from sliding sinusoidal fits ($\pm 5 \,\mu s$) to the recorded radial beam centroid, whereas solid lines result from multi-parameter fits through the entire fill. Both methods are equivalent.

On the other hand, a handful of potted resistors (which connect to ESQ plates as part of the RC circuitry) with HVRs in series were installed during Run-1 for logistical reasons [111] (see Fig. 3.62). Two of them, connected to the top and bottom long plates at ESQ station Q1 ("Q1LT" and "Q1LB"), were measured for several high voltages with a HV probe after Run-1 concluded and found to be damaged. Their HV traces were expected to behave like the nominal ones shown with thin lines in Fig. 3.63. However, measurements displayed longer relaxation times (circular markers in Fig. 3.63). Moreover, the peculiar HV traces from the damaged resistors manifested fluctuations over the course of the probe measurements, providing strong evidence of multimodal stages of the ESQ station Q1L during Run-1 (also reflected from tracker data shown in Figs. 3.60 and 3.61). The faulty behavior of these two resistors (out of all the thirty-two installed in the ESQ circuitry) indicated corona discharges on the resistor surface [112]; resistors outgassed while their temperature raised, leading to

Figure 3.61: Vertical centroid drifts during Run-1 from straw tracking detectors data. Solid lines are fits with double exponential terms and a constant part as the functional form.

the discharge at low voltages. The outgassing was likely more dramatic during the last and longest Run-1 dataset (1d), pushing the ESQ to produce more unusual electric guide fields.

In Sec. 3.6.1, a method to reverse-engineer the Q1LT- and Q1LB-HV traces per Run-1 dataset is elaborated. From the reconstruction results, derived optical lattice functions are presented in Sec. 3.6.2.

Section 3.6.3 describes a reliable method to reconstruct the beam 6D structure out of experimental data. Lastly, in Sec. 3.6.4 the stored muon beam from tracking simulations is presented, with the reconstructed HV traces and data-based initial beam conditions as input for the COSY-based model.

Figure 3.62: Single-CADDOCK high-voltage resistor (top) and chain of potted HV resistors (bottom). Two of the latter type of resistors became damaged during Run-1.

3.6.1 Reconstruction of the electric guide fields during Run-1

Technique

The electrostatic potential produced at an ESQ station can be represented as a superposition of the four contributions originated by each of its top "T", bottom "B", inner "I", and outer "O" plates. In addition to the potential $V_0(x, y, t)$ expected at ESQ-station Q1L under nominal conditions, an additional contribution $\Delta V_T(x, y, t)$ and $\Delta V_B(x, y, t)$ from the faulty Q1LT and Q1LB plates, respectively, during Run-1 is overlaid as a perturbation under the straight-plates approximation as follows:

$$\Delta V(x, y, t) = \Delta V_T(x, y, t) + \Delta V_B(x, y, t)$$

=
$$\sum_{k=0}^{\infty} \sum_{l=0}^{\infty} \left(\Delta H V_T(t) g_{k,l} + \Delta H V_B(t) b_{k,l} \right) x^k y^l$$
(3.75)

In Eq. (3.75), $\Delta HV_T(t)$ and $\Delta HV_B(t)$ are the extra high voltages "HV" on the top and bottom plates due to the damaged resistors in Run-1 such that the total HV traces are given

Figure 3.63: HV-traces sample (circle markers) from HV probe measurements in September 2018, at Q1L plates connected to the damaged resistors. Blue and red lines depict nominal HV traces.

by

$$HV_T(t) = HV_{0,T}(t) + \Delta HV_T(t)$$
 and $HV_B(t) = HV_{0,B}(t) + \Delta HV_B(t)$, (3.76)

where HV_0 is the nominal case. The coefficients $g_{k,l}$ and $b_{k,l}$ determine the distribution of $\Delta HV_{T,B}(t)$ among the top/bottom plate multipoles. Since $b_{1,0} = 0$, $b_{1,1} = 0$, and $b_{k,l} = (-1)^{k+l}g_{k,l}$ due to the orientation and 180° rotational symmetry of the top/bottom plates, Eq. (3.75) can be rewritten as

$$\Delta V(x, y, t) = \Delta V^s_{dip}(t)y + \Delta V^n_{quad}(t)(x^2 - y^2) + \cdots, \qquad (3.77)$$

where

$$\Delta V_{dip}^{s}(t) = \left[\Delta H V_{T}(t) - \Delta H V_{B}(t)\right] b_{0,1} \quad \text{and} \quad \Delta V_{quad}^{n}(t) = \left[\Delta H V_{T}(t) + \Delta H V_{B}(t)\right] b_{2,0}.$$
(3.78)

The study [89] provides the coefficients $b_{0,1}$ and $b_{2,0}$. Given the orthogonality of the two equations in Eq. (3.78) in terms of ΔHV_T and ΔHV_B , there is a unique set of top and bottom HV traces that yield $\Delta V^s_{dip}(t)$ and $\Delta V^n_{quad}(t)$. To evaluate these traces, the extra skew dipole $\Delta V^s_{dip}(t)$ and normal quadrupole $\Delta V^n_{quad}(t)$ terms must be linked to beam dynamic observables measured by the g-2 straw tracking detectors, as shown next.

Implementation

Under the presence of the extra vertical dipole electric potential $\Delta V_{dip}^{s}(t)$ (Eqs. (3.77) and (3.78)), the vertical closed orbit becomes distorted. Therefore, by measuring the distortion of the vertical closed orbit at one azimuthal location of the storage ring (aka vertical fixed points " y_0 ") over time, $\Delta V_{dip}^{s}(t)$ can be quantified. In fact, the straw trackers have the ability to extract such vertical beam equilibrium positions around specific locations within the ring.

To illustrate the relation between $\Delta V_{dip}^{s}(t)$ and the observable y_{0} (equivalent to the nonoscillating vertical mean from tracker data), the former variable can be treated as a dipole steering error [113]:

$$\begin{pmatrix} y \\ b \end{pmatrix}_{0} = \left(I - M_{0}^{y}\right)^{-1} \begin{pmatrix} 0 \\ \Delta \theta_{y} \end{pmatrix} , \quad \Delta \theta_{y} \approx -\frac{e\Delta V_{dip}^{s}}{E_{0}} \frac{l}{r_{ref}}$$
(3.79)

where M_0^y is the vertical quadrant of the storage ring transfer map without the steering

error, $\Delta \theta_y$ is the resulting vertical steering angle, E_0 the energy, r_{ref} the reference radius of ΔV_{dip}^s , and l is the length of the element that provides the steering error. It is worth mentioning that the linear vertical transfer map M_0^y has to account for the gradient error explained next.

The normal quadrupole extra term $\Delta V_{quad}^n(t)$ introduces a distortion to the radial defocusing gradient at Q1L. Consequently, the betatron tunes $\nu_{x,y}$ and beam transversal widths are affected due to the nonzero $\Delta V_{quad}^n(t)$. Trackers can indirectly measure the radial CBO frequency (see Fig. 3.60), ω_{CBO} , which relates to the tunes through the cyclotron frequency, f_C , via $\omega_{CBO} \approx 2\pi f_C(1 - \nu_x)$. In a similar fashion, the relation between $\Delta V_{quad}^n(t)$ and the observable ω_{CBO} can be elucidated by treating the action of $\Delta V_{quad}^n(t)$ as a gradient error [78]:

$$\nu_x = 1 - \frac{\omega_{CBO}}{2\pi f_C} = \frac{1}{2\pi} \left(4 \cos^{-1} \left(\frac{\text{Tr}(M_0^x)}{2} \right) + \frac{e \Delta V_{quad}^n}{pv} \frac{\beta_x l}{r_{ref}^2} \right),$$
(3.80)

where $\text{Tr}(M_0^x)$ is the trace of the horizontal quadrant of the storage ring transfer map without the gradient error. In reality, the action of the extra skew dipole and normal quadrupole terms at Q1L during Run-1 is entangled and magnetic field inhomogeneities already distort closed orbits. Moreover, trackers do not measure the vertical closed orbit at Q1L. Thus, the illustrative but simplistic equations (3.79) and (3.80) do not suffice to solve for $\Delta HV_{T,B}(t)$ via $\left(\Delta V_{quad}^n(t), \Delta V_{dip}^s(t)\right)$ with (y_0, ω_{CBO}) from tracker data. For this purpose, with the highfidelity COSY-based storage ring model and optimization algorithms supported by COSY
INFINITY [53, 54], a more representative set of bijective equations is prepared:

$$y_0(t) = F_1(\Delta H V_T - \Delta H V_B, \vec{A}; t), \qquad (3.81)$$

$$\omega_{CBO}(t) = F_2(\Delta H V_T + \Delta H V_B, \vec{A}; t).$$
(3.82)

With these relations fully established, the Q1LT and Q1LB high-voltage traces are reconstructed. The vector \vec{A} contains all the other nominal parameters of the storage ring independent of the bad resistors behavior. Fig. 3.64 illustrates the optimization process for one set of tracker measurements (y_0, ω_{CBO}) to obtain the optimal top and bottom HV-trace values at a specific time. In Fig. 3.64, right plot, " f_{obj} " is the sum of objective functions that the optimizer minimizes iteratively:

$$f_{obj,1} = \left(1 - \frac{\nu_x^{sim}(\Delta HV_T, \Delta HV_B)}{\nu_x^{\text{Tracker data}}}\right) \quad \text{and} \quad f_{obj,2} = \left(1 - \frac{y_0^{sim}(\Delta HV_T, \Delta HV_B)}{y_0^{\text{Tracker data}}}\right),$$
(3.83)

where the superscript "sim" stands for the values from the COSY-based model, dependent on the ΔHV_T and ΔHV_B values input to the model.

Reconstruction Results

Fig. 3.65 presents the HV traces from Q1LT and Q1LB during Run-1 datasets as reconstructed with the method described above. For the time window prior to the nominal measurement start time, $t < 30 \,\mu$ s, the HV-traces reconstruction fails to output results that resemble the functional forms as directly measured with the probe. To bypass such limitation, the functional form of the reconstructed HV traces at $t > 30 \,\mu$ s is extended to fill out the gap at $t < 30 \,\mu$ s. The implementation of the reconstructed HV traces is validated

Figure 3.64: High voltage on Q1LT and Q1LB plates (left) and objective function (right) per iteration as the optimization takes place for the Run-1, EndGame dataset, at 40 μ s. The optimizer supported by COSY INFINITY (i.e., the generalized least squares Newton method) fits Q1LT/Q1LB HVs such that the COSY-based storage ring model with damaged resistors accounted for reproduces a vertical fixed point (equivalent to the vertical mean) and CBO frequency as measured by tracker station 12.

Figure 3.65: Reconstructed HV traces (normalized to their nominal voltage set-points) at Q1L during Run-1 datasets. Dashed and solid lines correspond to Q1LT and Q1LB plates, respectively.

by comparing beam tracking simulation results with tracker data, i.e., CBO frequencies and vertical centroids over time as shown in Fig. 3.66.

Figure 3.66: Comparisons between tracker data (blue markers) and tracking simulations (red markers) at tracker S12 azimuthal readout location with the damaged-resistors effect implemented. On the left is the CBO frequency, whereas on the right vertical centroids are shown. Similarly, strong agreements are obtained for the other Run-1 datasets. For comparison purposes, the vertical entries on the right plot are shifted within tracker misalignment errors.

Cross checks and uncertainty estimation

The HV-traces reconstruction raises from the observation of slowly changing beam parameters (CBO frequency and vertical mean) at the azimuthal locations in the ring where trackers take data from. The CBO frequency is a global parameter independent of the ring location, as it is directly related to the betatron tunes, and its direct extraction from radial beam oscillations and functional fits has demonstrated to be reliable. On the other hand, the early-to-late vertical mean drift is more subject to the limited statistics of the available data, especially at late times in the fill. To compensate for this aspect, vertical mean drifts as recorded by calorimeters around the ring serve as an extra input to constrain the equilibrium vertical mean after the effect of the damaged resistors during the fill, this way guaranteeing the overall vertical drifts from tracker data.

Figure 3.67: Black markers are vertical beam drifts (40-300 μ s) from calorimeter data (energy threshold of 1.7 GeV) under material-effect corrections, where double exponential fits were employed. In blue, vertical closed orbit distortion drifts from 40-300 μ s using the COSY-based model with the reconstructed HV traces implemented. The blue error band is an estimate of the uncertainty introduced by the vertical dispersion. The red squares are from a GM2RINGSIM muon tracking simulation [45] with an implementation of the electric guide fields reconstructed with the COSY-based model. The simulations are matched to data by associating the closed orbit placed ~ 22° upstream of the calorimeter position.

Moreover, several aspects from the storage ring modeling that could interfere with the sensitivity of the vertical beam mean and CBO frequency to changes in the guide fields were considered [114], namely:

- Magnetic multipole coefficient errors from Trolley data (not greater than 300 ppb).
- HV reconstruction based on data from tracker station S12 vs. S18.
- Ambiguity of magnetic field reference azimuthal angle.

The largest impact of the listed effects on the reconstructed HV traces came from magnetic coefficient errors and, for instance, their corresponding optical lattice functions led to systematic errors of the phase acceptance correction of about 1 ppb.

The presence of a third damaged resistor at station Q3L was also suspected. However, when a reconstruction of three traces was attempted under these conditions (information of the vertical beam at the two tracker stations was accounted for simultaneously, to consider three optimization objective functions), the optimization method did not converge to physical results. At a qualitative level, HV measurements of the third possible plate to have been damaged during Run-1 exhibited a stable behavior after the fit start time [111]. Also, comparisons shown in Fig. 3.67 considering two damaged resistors recreate calorimeter observations within experimental errors.

3.6.2 Optical lattice functions during Run-1

With the reconstructed HV traces at Q1LT and Q1LB for each Run-1 dataset, the total electric potential at Q1L is defined in the COSY-based model and optical lattice functions prepared (see Sec. 3.3.2).

Figure 3.68 shows how vertical closed orbits are shifted due to the effect from damaged resistors. The minimum distortion on the vertical orbit occurs at Q1L, where the steering error is located. At the opposite side of the ring, the vertical closed orbit suffers its largest drift. A similar pattern arises from the vertical beta functions beating (see Figs. 3.69 and 3.72). The ring is a closed system where extra steering or gradient errors beyond design have global implications on the entire lattice. For instance, while muons cross the mispowered station Q1L, the lower focusing vertical gradient lets the beam spreads out to a larger amount than the design case, wherein vertical beta functions reflect a proportional azimuthal evolution.

On the radial end, larger radial tunes change the resulting patterns driven by Q1L during Run-1 (see Figs. 3.70 and 3.71). The radial closed orbit is minimally affected by the damaged resistors; the top and bottom plates at Q1L do not introduce normal dipole electric fields.

As the Q1LT and Q1LB plates slowly converge to the nominal HV setting, all optical

Figure 3.68: Vertical closed orbits at 30 μ s (red curves), 100 μ s (blue curves), 200 μ s (green curves), and 300 μ s (black curves) during Run-1. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. Red curves are subject to the effects of the ESQ scraping configuration and the green curves have almost reached the equilibrium values.

Figure 3.69: Vertical beta functions at 30 μ s (red curves), 100 μ s (blue curves), 200 μ s (green curves), and 300 μ s (black curves) during Run-1.

functions adiabatically converge to a stable state. Figure 3.73 shows the time evolution of the lattice at 210° from the upstream entrance of station Q1S (Run-1 dataset 1d), where the lattice gradients are the largest.

With these dataset-by-dataset periodic functions of the optical lattice, tracker data is extrapolated around the ring (see Sec. 3.5.3). Figure 3.74 displays the beam centroids and widths based on tracker data (EG), station 12.

Figure 3.70: Radial beta functions at $30 \,\mu s$ (red curves), $100 \,\mu s$ (blue curves), $200 \,\mu s$ (green curves), and $300 \,\mu s$ (black curves) during Run-1.

3.6.3 Initial beam distributions

The muon g-2 straw tracking detector system has the beam-diagnosis capability of recording radial x and vertical y muon coordinates to resolutions of $\sigma \approx 4 \text{ mm}$ and time t coordinates with 3.4 ns precision during Run-1 [38].

In the stroboscopic perspective, tracker measurements can be treated as localized in a well-defined azimuthal location as a result of the narrow azimuthal sensitivity ($\approx 4.9^{\circ}$) and the weakly focusing optics approximation. In this view, the radial motion of the beam is modeled for small time ranges as an ensemble of monochromatic muons oscillating at a common radial CBO frequency ω_{CBO} with different equilibrium positions x_{e}^{i} , betatron

Figure 3.71: Radial dispersion functions at $30 \,\mu s$ (red curves), $100 \,\mu s$ (blue curves), $200 \,\mu s$ (green curves), and $300 \,\mu s$ (black curves) during Run-1.

amplitudes A_j , and phases ϕ_k :

$$x(t) = x_{e}^{i} + A_{j} \cos\left(\omega_{CBO}t + \phi_{k}\right).$$
(3.84)

The measured data-bin intensity N_{mn} at coordinates (x_m, t_n) —see Fig. 3.75—can be expressed as [115]

$$N_{mn} = \sum_{i=1}^{n_i} \sum_{j=1}^{n_j} \sum_{i=k}^{n_k} \beta_{ijkmn} f_{ijk}, \qquad (3.85)$$

where f_{ijk} is the relative muon population identified by the set $\{x_e^i, A_j, \phi_k\}$ from the beam probability density function (PDF) $f(x_e, A, \phi)$. In Eq. (3.85), the summation upper bounds

Figure 3.72: Relative vertical beta functions drift from $30 \,\mu s$ to $1000 \,\mu s$.

correspond to the number of values subject to the binning size along each coordinate in f_{ijk} (e.g., $n_i = 45$ for $x_e^1 = [-45, -43]$ mm, $x_e^2 = [-43, -41]$ mm, ..., $x_e^{45} = [43, 45]$ mm).

On the other hand, the relative number of muons with specific $(x_{e}^{i}, A_{j}, \phi_{k})$ coordinates that contribute to the measured intensity N_{mn} , symbolized by β_{ijkmn} in Eq. (3.85) and not to be confused with betatron functions, is equal to the probability of such muons to be found at the bin (x_{m}, t_{n}) :

$$\beta_{ijkmn} = \int_{x_m=r_-}^{r_+} \int_{t_m=t_-}^{t_+} \frac{\epsilon (x_m)}{\sqrt{2\pi\sigma}} e^{-\frac{1}{2\sigma^2} \left[x_m - \left(x_e^i + x_{off} + A_j \cos(\omega_{CBO} t_n + \phi_k) \right) \right]^2} dx_m dt_n.$$
(3.86)

The radial acceptance $\epsilon(x)$ in Eq. (3.86) [38] accounts for detection effects of the tracker stations. The offset x_{off} is determined based on data and accounts for closed orbit distortions, tracker reconstruction offsets, and tracker misalignments.

With these well-established relations between beam PDFs and x - t tracker data, the

Figure 3.73: β_x , β_y , D_x , and vertical closed orbit at 210° from the upstream entrance of station Q1S for dataset Run-1d.

optimal f_{ijk} functions can be estimated via non-negative least squares (NNLS) minimization of the following χ^2 expression:

$$\chi^{2} = \sum_{m=1}^{n_{m}} \sum_{n=1}^{n_{n}} \frac{\left(\sum_{i,j,k} \beta_{ijkmn} f_{ijk} - N_{mn}\right)^{2}}{\sigma_{Nmn}^{2}}.$$
(3.87)

Under constraints inspired by further data analysis, the minimization converges to physical solutions after less than 10,000 iterations. For instance, the FR signal [51] enables to limit the conditional PDF $f(x_e|A, \phi)$, wherein resulting deviations from the original signal can be attributed to differences between calorimeter and tracker detection efficiencies.

Figure 3.74: Beam drifts from 40 μ s to 300 μ s anchored to tracker data for the Run-1d dataset. Gray shadows depict ESQ stations along the azimuth, where the Q1S upstream edge is at $\theta = 0$. Orange lines indicate collimator locations. With the Run-1 optical lattice functions, the observed beam drifts measured by the muon g-2 straw tracking detectors are projected along the entire azimuth of the storage ring.

Figure 3.76 shows a typical $f(x_e, A, \phi)$ function projected along two dimensions. Correlations between x_e , A, and ϕ are expected to result from the dynamics caused by the injection, collimation, and circulation of the muon beam in the storage ring [116].

Thanks to the periodicity of the mismatched beam motion over time, a data range of one CBO period is sufficient to reconstruct the beam conditions (and necessary to ignore betatron tune shifts). In order to capture the beam scraping process (an essential component for realistic muon loss rates modeling) that took place during Run-1 the PDFs are calculated from data at around 4 µs after injection while the scraping scheme is at its initial stage.

From the vertical-motion front, the reconstruction follows the same process as for the radial case with a simplification of all vertical oscillations following the same fixed point in

Figure 3.75: Resolution- and acceptance-corrected radial position versus time from tracker data, Station 12. By reconstructing the trajectory of decay positrons detected by the tracking planes, muon decay positions are extrapolated. Coherent oscillations are a consequence of the beam injection process.

the absence of vertical dispersion. Specifically, the vertical distribution of the muon beam is described with vertical betatron functions and constant oscillation offsets.

The initial time profile of the beam is set based on measurements from scintillating detectors. With the COSY-based model, which includes the observed injection-kicker ringing pattern during Run-1 and a realistic beam distribution at injection (see Sec. 3.2.5), a correlation between time and momentum offsets is assigned to the initial beam distribution at $4 \mu s$.

Using the linear beam dynamics framework, the initial \vec{z}_i ray coordinate sets are prepared for each muon from the reconstructed PDFs for nonlinear beam tracking simulations with the COSY-based model.

Even though nonlinearities are not considered in the reconstruction of the initial beam

Figure 3.76: Reconstructed beam distribution in the radial direction. On the left plot, the upper limits are determined by the physical apertures of the collimators which bound maximum radial excursions, whereas the maximum kicker strength defines the lower limits.

conditions, all the de-coherence, betatron amplitude modulation, and tune-dependent shifts originated by the higher order guide fields are manifested in the nonlinear beam tracking simulations.

This reconstructed method assumes no correlations between the radial and vertical motion, which agrees with observations from the straw tracking detectors. Sufficiently large skew quadrupole coefficients from the electric and magnetic fields can potentially introduce x-y beam correlations, and proper modeling of these fields in the simulation gives rise to such effects.

3.6.4 The simulated Run-1 beam

The following features developed in this dissertation set the stage for a highly realistic recreation of the stored muon beam during Run-1:

- COSY-based model of the muon g-2 storage ring.
- Reconstructed ESQ fields at station Q1L based on experimental data.
- Realistic initial beam distribution based on experimental data.

Figure 3.77: Muon beam intensity from simulation (left) and tracker data (right), station 12, during Run-1a from $30 \,\mu s < t < 300 \,\mu s$.

By performing symplectic tracking, the beam information is regenerated at arbitrary azimuthal locations. With these distributions—and the optical lattice functions from the COSY-based model—, beam dynamics systematic uncertainties in the muon g-2 experiment are assessed to the precision demanded by the objectives of the experiment (see Chap. 4). To validate the results derived from this analysis, experimental data are used to compare results from tracking. Figures 3.77-3.81 show examples.

In Fig. 3.77, the transverse profile of the beam at tracker station 12 is shown during Run-1a, integrated from $30 \,\mu\text{s} < t < 300 \,\mu\text{s}$. The characteristic radial structure dictated by correlations between the muon dynamic parameters (momentum-dependent fixed points, betatron phases, and betatron amplitudes) is captured in the simulated beam. The vertical projection, which resembles more closely a normal distribution, is also well represented in the numerical results. Figure 3.78 shows the corresponding projections in Fig. 3.77 2D distributions. Due to either an imperfect simulated scraping process during the first microseconds

Figure 3.78: Muon beam intensity projections from simulation (red) and tracker data (blue), station 12, during Run-1a from $30 \,\mu s < t < 300 \,\mu s$.

Figure 3.79: Radial beam evolution over time from tracker S12 data (top) and simulated beam (bottom) during Run-1a. The data-driven reconstruction of the initial beam conditions allows to capture in beam tracking simulations (in this case with the COSY-based model) the transverse and temporal evolution of the observed beam.

Figure 3.80: Radial CBO frequencies from simulated beam (red) and tracker data (blue) for each Run-1 dataset.

after beam injection or tracker data resolution, discrepancies smaller than 2 mm are evident in the radial case. Figure 3.79 shows the radial beam motion over time at tracker station 12 (Run-1a).

The measured CBO radial frequency is closely followed in the simulated beam thanks to the implementation of the reconstructed HV traces at ESQ plates Q1LT and Q1LB, which serves as a closure test. CBO radial frequencies are shown in Figure 3.80.

The beam centroid drifts from simulations are also reproduced (see Fig. 3.81). Results from tracker data and simulations are shifted vertically for the intended comparison of gradients. Without the introduced offsetting, data and simulations agree within the vertical

Figure 3.81: Vertical centroid from simulated beam (red) and tracker data (blue), station 12 for each Run-1 dataset.

alignment uncertainty of the straw trackers ($\sim 0.6 \text{ mm}$).

The agreement of the momentum spread from simulated Run-1 beams with results from the FR analysis is also strong since the latter was one of the inputs to prepare initial muon beam distributions (see Sec. 3.6.3). Several efforts within the muon g-2 collaboration were carried out to validate the beam extrapolated as presented in this document with data calorimeter detectors. An example of this collective effort is Fig. 3.67. However, in contrast with the straw tracking detection system and its specialized design to measure the muon beam, the task is daunting since calorimeters measure positron energies and arrival times and not the transverse coordinates of muons where positrons originated in the first place.

3.7 Conclusions

In this chapter, the developed COSY-based model of the muon g-2 storage ring was presented. The model allows for preparations of realistic tenth-order transfer maps used for a detailed characterization of the muon beam stored in the ring via calculations of optical lattice functions and symplectic tracking simulations. The detailed implementation of the electric and magnetic fields based on measurements and modeling allows capturing both the linear and nonlinear behavior of the stored beam.

With the presented linear framework wherein nonlinearities permeated the results on some occasions, the optical lattice functions of the ring (including closed orbits) are prepared and, furthermore, their validity is tested to describe the beam reliably for the case of the g-2 storage ring. On the other hand, the assessment of nonlinearities permitted to build a detailed description of amplitude- and momentum-dependent tune shifts, as well as their implications on beam de-coherence, betatron resonances, and lost muons due to betatron amplitude modulations.

A nominal characterization of the typical beam injected into the ring was also performed, which is used in the experiment to extrapolate the measured beam transverse intensity to the full azimuthal span. With the modeling of the injection kickers as part of the COSY-based storage ring, the largest systematic uncertainty of the E-field correction is quantified.

The special behavior of the ESQ during Run-1 was reproduced numerically via optical lattice functions and symplectic tracking thanks to the developed method to reconstruct fields at the damaged ESQ station based on experimental data. Furthermore, the elaboration of a method to define initial beam conditions from available data allowed to reproduce with high fidelity the Run-1 beam beyond data, used for systematic correction studies at E989.

Chapter 4

Beam Dynamics Correction Studies

4.1 Introduction

As presented in Sec. 1.3, the dynamical properties of the stored beam from which the anomalous magnetic moment of the muon a_{μ} is indirectly measured introduces ppb-level systematic corrections to the *measured* anomalous precession frequency ω_a [45]. Applications using the beam characterization developed with the COSY-based model of the muon g-2 storage ring (see Chap. 3) aimed at quantifying those corrections and their uncertainties are presented in this chapter.

To initiate the discussion of the aforementioned corrections, it is appropriate to start with the nominal case. In this idealized case of perfect circular motion and the ESQ stations turned off, ω_a is equal to the nominal g-2 frequency ω_{a0} :

$$\omega_{a0} \equiv -a_{\mu} \frac{eB_0}{m_{\mu}},\tag{4.1}$$

where the magnetic field \vec{B}_0 is vertical and constant in magnitude. The four beam dynamics systematic corrections—necessary to carry ω_{a0} towards the reality of the beam stored in the g-2 storage ring to a ppb-level precision—are symbolized and identified as follows:

• C_{ml} : Muon loss correction.

- C_{pa} : Phase acceptance correction.
- C_e : E-field correction.
- C_p : Pitch correction.

With these systematic corrections properly quantified, the measured frequency ω_a is unbiased and the true a_{μ} calculated ¹:

$$a_{\mu} = -\frac{m_{\mu}}{e\tilde{B}}\omega_{a0}$$

$$= \frac{m_{\mu}}{e\tilde{B}}\omega_{a}\left(1 + C_{ml}\right)\left(1 + C_{pa}\right)\left(1 + C_{e}\right)\left(1 + C_{p}\right)$$

$$\approx \frac{m_{\mu}}{e\tilde{B}}\omega_{a}\left(1 + C_{ml} + C_{pa} + C_{e} + C_{p}\right),$$
(4.2)

where \tilde{B} is the average magnetic field weighted by the muon beam [39] instead of simply B_0 , due to the beam transverse profile and magnetic field inhomogeneities. As shown in Sec. 4.5, the azimuthal characterization of the beam presented in Chap. 3 is utilized to weight the measured magnetic field with the muon beam around the ring. For reference, the Run-1 beam dynamics corrections are listed in Table 4.1.

 C_{ml} and C_{pa} are intrinsic to the experimental technique used in the muon g-2 experiment, wherein ω_a is extracted from fitting the time-dependent detected number of positrons above energy threshold (see Sec. 1.2.1) with a sinusoidal multi-parameter functional form [33] proportional to

$$\cos\left(\omega_a t + \varphi_0\right). \tag{4.3}$$

As explained in Sec. 1.3, an overall change in the g-2 Phase φ_0 during the data taking

¹The muon g-2 experiment measures the scalar magnitude ω_a , for which the negative signs are removed in the right-hand side of the last two lines in Eq. (4.2).

Table 4.1: The Run-1 beam dynamics corrections [45]. The C_{ml} and C_{pa} corrections are anticipated to be significantly smaller for runs posterior to Run-1 where the ESQ fields are expected to behave stably during data taking. The E-field correction C_e counteracts the largest biasing in ω_a due to additional spin precessions of stored muons away from magic momentum.

	Correction [ppb]	Uncertainty [ppb]
C_e	489	53
C_p	180	13
C_{ml}	-11	5
C_{pa}	-158	75
Total	499	93

period (i.e., $\sim 30 \,\mu\text{s} < t < 700 \,\mu\text{s}$ after beam injection) is indistinguishable and quietly absorbed by the extracted ω_a from the χ^2 -minimization fit. When the physical meaning of φ_0 is accounted for, it does become time dependent due to lost muons and momentum-spin correlations; the magnitude of these two beam properties can lead to non-negligible muon loss corrections. In Sec. 4.2, a simulation-driven calculation of the C_{ml} correction during Run-1 with the COSY-based model is presented.

On the detection side, the g-2 phase is in fact an observable derived from positrons that are detected in the experiment [44]. Out of each transverse location, positrons are emitted within a decay cone which, due to finite calorimeter acceptance, is not entirely detected most of the cases. The distribution of detected phases over the decay cone is not uniform since the initial directions of the positrons are correlated with the spin direction of muons prior to the decay. Therefore, the observed g-2 phase depends on the transverse distribution of the muon beam. During Run-1, the transverse profile of the muon beam exhibited drifts over the data taking period (see Sec. 3.6). Consequently, the g-2 phase also varied (see Sec. 4.3). This effect introduces the C_{pa} correction. Section 4.3 elaborates on the multiple efforts from the beam dynamics side that were performed as part of this dissertation to quantify the C_{pa} correction, which became relevant during Run-1 due to the faulty ESQ behavior (posteriorly repaired).

On the other hand, C_e and C_p directly bias the measured precession ω_a without the intervention of the g-2 phase. Instead, these corrections encapsulate the first-order effects of vertical motion and momentum spread on the spin dynamics relative to the cyclotron beam motion, for which the expression of the nominal g-2 frequency ω_{a0} is not sensitive. As shown in Sec. 4.4, the standard expressions of C_e and C_p were tested with the COSY-based model beyond the assumptions on which they were derived for previous versions of the muon g-2 experiment (i.e., CERN III and BNL).

4.2 The Muon Loss Correction

4.2.1 Momentum-phase correlations

In real terms, φ_0 in Eq. (1.25) represents the overall angle between the beam spin polarization and its momentum at t = 0, i.e., the precession-fit reference time which corresponds to the moment when the beam is injected into the storage ring:

$$\varphi_0(t) = \frac{1}{N_s(t)} \sum_{i=1}^{N_s(t)} \varphi_{0,i}, \qquad (4.4)$$

where $N_s(t)$ is the number of stored muons at time t and $\varphi_{0,i}$ the individual phase of a muon within the stored beam.

For this reason, if there are lost muons (see Sec. 3.4.3) whose individual phases are correlated with their momenta and, in addition, the stored beam relative-momentum average $\langle \delta \rangle$ is sensitive to muon loss, then a time-dependent phase sufficiently large to bias ω_a can potentially emerge (see Eq. (1.29)):

$$\Delta\varphi_0(t) = \frac{d\varphi_0}{d\langle\delta\rangle}\Big|_{t=0} \langle\delta\rangle(t) = m_\delta\langle\delta\rangle(t).$$
(4.5)

As explained in Sec. 2.3.4, due to dispersive effects and the momentum compaction factor in the Delivery Ring, high-momentum muons experience greater integrated magnetic dipole fields along their trajectories. Thus, their spins precess larger angles in the midplane in comparison to low-momentum muons. This effect leads to $\varphi_0 - \delta$ correlations. From simulations of the Beam Delivery System (BDS) described in Chap. 2 (Fig. 2.16), the beam linear correlation between the g-2 phase and the Lorentz factor γ is $m_{\gamma} = 29.2 \pm 9.4$ mrad. In terms of δ as in Eq. (4.5), from $m_{\delta} \approx \gamma_0 \beta_0^2 m_{\gamma}$ (derived in turn from $p = \gamma m \beta c$) the $\varphi_0 - \delta$ linear correlation is

$$m_{\delta} \approx 8.79 \pm 2.8 \,\mathrm{mrad}/(\%\delta),$$
(4.6)

where "% δ " denotes momentum offsets in units of percentage. Results in agreement with Eq. (4.6) from external tracking simulations of the Muon Campus [117] are used instead for the following simulation-based calculation of C_{ml} . The correlation derived from this work is shown in Fig. 4.1.

4.2.2 Momentum spread subject to lost muons

The other ingredient to numerically reproduce the changing phase from muon loss is the evolution of the beam momentum average. For this purpose, the momentum spread from tracking simulations for each of the Run-1 datasets with the COSY-based model (described in Sec. 3.6.4) is numerically traced as muons get lost during the data-taking period in the

Figure 4.1: Momentum dependence of the initial g-2 phase φ_0 . The simulations (black plot markers) are in good agreement with experimental data (blue, preliminary). The experimental data were obtained by studying the behavior of muons with momenta above and below the magic momentum in the storage ring [118].

simulation.

In general, the momentum compaction in the storage ring yields a longitudinal dilution as shown in Fig. 4.2. Even though the overall momentum spread is diluting in time, as can be observed at any given azimuthal location, this effect does not introduce a slowly changing momentum profile; for time intervals of the order of a cyclotron period as used in positron signals to extract ω_a , the average momentum does not change.

On the other hand, muon losses cause a lasting momentum dependence when their overall momentum is not the beam's momentum average. Run-1 muon loss rates were low, but large enough to produce a 10 ppb-level systematic error as indicated by dedicated measurements [45] and the beam tracking simulations presented in this section. Figure 4.3 displays muon loss fractions from simulations and data.

Notwithstanding the comparable muon loss fractions between measurements and simula-

Figure 4.2: Momentum spread over time from Run-1d tracking simulations at early and late times. While the beam spreads in the longitudinal direction, muons with different momenta combine together.

Figure 4.3: Muon loss rates versus time, 30 µs after injection, from symplectic tracking Run-1 simulations (left) and data (right, [119]). The $3\nu_y = 1$ resonance nearby Runs 1a and 1d increases the loss fraction (Sec. 3.4.3). Uncertainty bands on the curves from data accounts for experimental scaling errors in the determination of muon loss rates.

tions, differences arise from the implementation in the COSY-based model of outdated radial magnetic field data, a single implementation of the trolley run measurements for all Run-1 datasets, and gain correction uncertainties from the data-taking front.

Several factors influence the relative amount of muon losses. In particular, while the Run-1a and Run-1d datasets operated at a nominal ESQ set-point of HV = 18.3 kV near the $3\nu_y = 1$ resonant condition, the other Run-1 datasets (HK and 9d) operated at HV = 20.4 kV, farther from the nearest resonant conditions of $HV \approx 18.6 \text{ kV}$ and $HV \approx 21 \text{ kV}$ (see Sec. 3.4.3). For this reason, muon loss rates were lower for HK and 9d datasets. Moreover, the larger the number of inserted collimators, the more likely a muon—either with a modulated betatron amplitude from nonlinearities or not—is to hit a collimator and get lost faster, yielding less lost muons at later times. The initial beam distribution that results from the injection process also determines the population of muons prone to be lost (e.g., outermost muons), thus becoming an important factor in this regard.

Off-momentum muons oscillate around fixed points closer to the limiting collimator apertures as indicated by radial dispersion functions. This effect exacerbates muon losses, as shown in Fig. 4.4.

4.2.3 The correction C_{ml} from the Run-1 simulated beam

Depending on the betatron amplitude beam distributions and the number of muons with largest momentum offsets, the average momentum of lost muons does modify the overall momentum spread of stored muons though to a low extent, as shown in Fig. 4.5. With m_{δ} and $\langle \delta \rangle(t)$ evaluated, the relative shift of the phase $\Delta \varphi_0(t)$ with respect to the phase at $t = 30 \,\mu$ s is estimated; results are shown in Fig. 4.6.

Monte Carlo (MC) simulations are prepared to reproduce histograms from which ω_a is

Figure 4.4: Relative momentum offsets of lost muons from Run-1 symplectic tracking simulations ($30 \ \mu s < t < 300 \ \mu s$). The vertical axis indicates the number of lost muons (in arbitrary units) per bin of momentum offset.

Figure 4.5: Stored beam's average momentum offset, relative to magic momentum, over time from tracking simulations with the COSY-based model.

Figure 4.6: *g*-2 phase time evolution from Run-1 symplectic tracking simulations driven by lost muons. The beam injection scheme and operational set-points lead to different functional forms per Run-1 dataset.

extracted in the experiment, where the generation of events is obtained from a 5-parameter functional form similar to Eq. (1.25):

$$N(t) = N_0 \cdot e^{-t/\gamma_0 \tau} \{ 1 + A \cos \left[\omega_a t - (\varphi_0 + \Delta \varphi_0(t)) \right] \}.$$
(4.7)

The parameters N_0 , $\gamma_0 \tau$, A, ω_a , and φ_0 are constants and the value taken for ω_a in the MC simulation is 1.43729 MHz. The resulting histogram is fitted back with the same generating function, although the phase is a simple parameter with no time dependence. The frequency ω'_a that minimizes the χ^2 -fit performed to MC data is taken in order to calculate the muon loss systematic correction as ²

$$C_{ml} = -\frac{\left(\omega_a' - \omega_a\right)}{\omega_a}.\tag{4.8}$$

²For a convention where the phase is accompanied by a negative sign in the functional form, the C_{ml} sign is reversed, too.

Results from each of the COSY-based Run-1 tracking simulations are shown in Table 4.2, which are within < 12 ppb away from data-driven results [45].

Table 4.2: ω_a corrections due to muon losses from beam tracking simulations. Errors for each calculation are produced after considering the measured spin-momentum correlation uncertainties and simulation statistical limits.

	C_{ml} [ppb]
Run-1a (60h)	-14.13 ± 4.30
Run-1b $(9d)$	2.18 ± 2.86
Run-1c (HK)	4.16 ± 4.47
Run-1d (EG)	-24.57 ± 2.47

4.3 The Phase Acceptance Correction

Similar to the muon loss correction C_{ml} , drifts of the g-2 phase φ_0 during the data taking period bias the measured anomalous precession frequency ω_a . As explained in the introduction of this chapter, the phase acceptance correction C_{pa} accounts for phase changes from the detection side rather than its physical meaning. From the parity-violating muon decay $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$, highest energy positrons are emitted in the muon spin direction with a probability proportional to the angle between these two directions. On the other hand, the positron emitted direction together with its energy and initial transverse coordinates in the storage volume determine whether it is detected by a calorimeter or not (see Fig. 4.7, right side, for a typical calorimeter acceptance map). Therefore, since the g-2 phase carried by a positron is indirectly related by its initial direction due to the parity-violating decay process, positron transverse decay coordinates and g-2 phases are correlated. Phase acceptance maps in transverse x-y planes along the storage region are prepared by Khaw *et al.* [44] with a GEANT4-based simulation program named GM2RINGSIM [120]. The model includes decay modules as well as all of the active detectors and most of the passive components installed in the storage ring, which allows recreating with high detail material effects that emitted positrons experience from their initial coordinates to the calorimeter locations. Figure 4.7 shows typical phase- and detection-acceptance maps prepared with the GM2RINGSIM model.

Figure 4.7: Typical detected-phase $\varphi_{0,k}$ (left) and calorimeter acceptance $\varepsilon_{c,k}$ (right) maps from GM2RINGSIM [44]. In the phase map, values indicated by the color legend (in mrad) are relative to a central g-2 phase defined at injection. 1 µrad phase shifts over a muon lifetime in the laboratory frame induce ω_a shifts of about 10 ppb.

Under normal conditions, the stored beam—although it may exhibit fast beam and width betatron oscillations due to beam mismatch—is expected to maintain a constant transverse distribution on the time scales of data taking periods (i.e., $30 \ \mu s < t < 700 \ \mu s$) under the effects of a stable optical lattice. If ESQ specifications are met, such scenario is expected [121] and the overall detected phase remains unchanged over the measurement (i.e., $C_{pa} = 0$). Nevertheless, sufficiently large muon loss rates can potentially induce vertical width beam drifts after the nominal fit start $t = 30 \ \mu s$ posterior to injection (see Fig. 3.52). Another potential mechanism that could introduce a changing detected phase owing to beam drifts are amplitude modulations from betatron resonances. However, muon loss studies with the COSY-based model (see Sec. 3.4.3) indicate that stored muons under these modulations exhibit periodic patterns around 3-period fixed points but do not coherently grow nor decrease to induce slow beam transverse gradients; if they get collimated, their effect potentially adds to the phase acceptance correction via beam width drifts instead. Regardless of any of these mechanisms, the g-2 straw tracking detectors [38] high-resolution measurements encapsulate the information required to quantify beam drifts at their two readout azimuthal locations. This was the case during Run-1, where the unstable optical lattice produced slowly changing beam centroids and widths beyond $t = 30 \,\mu s$ (see Sec. 3.6).

A method was needed to be developed in order to systematically quantify phase acceptance corrections during the analysis of Run-1 datasets. For this purpose, a multi-disciplinary task force within the muon g-2 collaboration was established [44], wherein the author of this dissertation participated in the determination of methods to extract C_{pa} from tracker data (Sec. 4.3.1), in the distinction of the main mechanisms that drive these corrections (Sec. 4.3.2), and in the extrapolation of phase drifts from tracker data to the entire storage ring (Sec. 4.3.3).

4.3.1 Extraction of phase drifts

At a given calorimeter c_k , where $k = \{1, 2, ..., 24\}$ denotes the calorimeter number, the number of detected positrons above energy threshold

$$N_{k}(t) = N_{0,k}e^{-t/\tau} \left[1 + A_{k}\cos\left(\omega_{a}t + \varphi_{0}^{c_{k}}(t)\right) \right]$$
(4.9)

arises from positrons emitted at transverse coordinates (x_i, y_j) within the storage region. The detected signal from each transverse location $N_{ijk}(t)$ is equal in form to Eq. (4.9) as follows [122]:

$$N_{ijk}(t) = M_{T,k}\left(x_i, y_j, t\right) \varepsilon_{c,k}\left(x_i, y_j\right) e^{-t/\tau} \left[1 + A_k(x_i, y_j) \cos\left(\omega_a t + \varphi_{0,k}\left(x_i, y_j\right)\right)\right],$$

$$(4.10)$$

where $M_{T,k}(x_i, y_j, t)$ is the relative muon beam intensity at (x_i, y_j) at calorimeter k readout location, $\varepsilon_{c,k}$ the acceptance that positrons emitted at (x_i, y_j) will hit calorimeter k and enter the $N_k(t)$ histogram, $A_k(x_i, y_j)$ is the asymmetry amplitude (see Eq. (1.24)), and $\varphi_{0,k}(x_i, y_j)$ the detected position-dependent phase at calorimeter k. In this view and considering

$$N_k(t) = \sum_{i,j} N_{ijk}(t),$$
 (4.11)

the total phase $\varphi_0^{c_k}(t)$ detected by the k^{th} calorimeter is the phasor addition of all the weighted transverse locations [44]:

$$\varphi_0^{c_k}(t) = \arctan \frac{\sum_{ij} M_{T,k}\left(x_i, y_j, t\right) \cdot \varepsilon_{c,k}\left(x_i, y_j\right) \cdot A_k\left(x_i, y_j\right) \cdot \sin\left(\varphi_{0,k}\left(x_i, y_j\right)\right)}{\sum_{ij} M_{T,k}\left(x_i, y_j, t\right) \cdot \varepsilon_{c,k}\left(x_i, y_j\right) \cdot A_k\left(x_i, y_j\right) \cdot \cos\left(\varphi_{0,k}\left(x_i, y_j\right)\right)}.$$
 (4.12)

Equation (4.12) constitutes the basis to estimate C_{pa} corrections in ω_a extracted from the *T*-Method [33] and is used to calculate detected phases in the following analysis. As observed from this equation, the detected phase develops a time dependence due to beam drifts accounted for in $M_{T,k}(x_i, y_j, t)$, which was indeed the case during all Run-1 datasets.

With Eq. (4.12), the phase, acceptance, and asymmetry maps from the GM2RINGSIM Team and, on the other hand, the measured beam intensity M_T at tracker azimuthal readout locations [86], the observed phase at nearby calorimeters (i.e., k = 13 and k = 19) can be extracted. The next step once $\varphi_0^{c_k}(t)$ is extracted is to determine the resulting shift on ω_a induced by the changing phase. For this end, three alternatives were analyzed to extract the slow component of the phase derived from Eq. (4.12) (Fig. 4.8 shows the detected phase from Eq. (4.12) and its corresponding slow component):

Figure 4.8: On the left side, the phase $\varphi_0^{c_{13}}(t)$ from the COSY-based Run-1a simulated beam and GM2RINGSIM maps (T-Method) via Eq. (4.12). On the right, the phase drift extracted from non-randomized window fits (black markers), which effectively capture the phase drift without the modulation induced by the beam coherent oscillations shown on the left plot. The red curve is a single-exponential fit to the resulting phase drift without modulation.

• Non-randomized, single fit [122]:

A functional form with all the oscillatory acceptance-induced components

$$\phi(t) = \varphi'_0 + \Delta \varphi e^{-t/\tau} + A_{CBO} e^{-t/\tau CBO} \sin(\omega_{CBO}(t)t + \phi_{CBO}) + A_{2CBO} e^{-2t/\tau CBO} \sin(2\omega_{CBO}(t)t + \phi_{2CBO}) + A_{VW} e^{-t/\tau VW} \sin(\omega_{VW}(t)t + \phi_{VW})$$

$$(4.13)$$

is fitted to $\varphi_0^{\mathbf{c}_k}(t)$ and use

$$\varphi_0' + \Delta \varphi e^{-t/\tau} \tag{4.14}$$

from the fit to represent the phase drift. The frequency $\omega_{CBO}(t)$ follows tracker data and

$$\omega_{\rm VW}(t) = \omega_{\rm c} - 2\sqrt{2k_{\rm VW} \cdot \omega_{\rm CBO}(t) \cdot \omega_c - k_{\rm VW}^2 \cdot \omega_{\rm CBO}^2(t)}$$
(4.15)

accounts for the aliased "vertical width" frequency $\omega_c - 2\omega_y$ [33]. For more details of the single fit, refer to [122].

• Randomized [108]:

Produce a beam profile $M_{T,k}(x_i, y_j, t')$ without the frequencies of the beam transverse motion $\omega_i = 2\pi/T_i$ by defining $t' = t + \sum_{i=1} ran_i$, where ran_i is a random number within $\{-T_i, T_i\}$. Use $M_{T,k}(x_i, y_j, t')$ in Eq. (4.12) to obtain the phase drift.

- Non-randomized, window fits [123]:
 - Fit ~ $\pm 8 \,\mu s$ segments of $\varphi_0^{c_k}(t)$ with the functional form

$$\phi_{i} = \varphi_{eq,i}$$

$$+ A_{CBO,\tau} \sin (\omega_{CBO}t + \varphi_{CBO})$$

$$+ A_{2CBO,\tau} \sin (2\omega_{CBO}t + \varphi_{2CBO})$$

$$+ A_{VW,\tau_{VW}} \sin (\omega_{VW}t + \varphi_{VW})$$
(4.16)

and use $\varphi_{eq,i} \mbox{'s}$ from the fits to define the slow drift.

From Run-1a simulated data with the COSY-based model (see Sec. 3.6.4), it was established that detector acceptance effects damage the randomization procedure to extract

phase drifts [123], as shown in Fig. 4.9. Analysis performed by Mott [124] determined the

Figure 4.9: Extracted drifting phases from all extraction methods. On the left, all methods agree when detector acceptance is absent. On the right plot, the randomized method does not capture the phase drift from radial CBO de-coherence, which emerges under the presence of nonuniform detector acceptance.

cause of the misleading phase drifts from randomization to be radial de-coherence; as the acceptance of the beam is subject to the coherent betatron motion in the radial direction, the slow de-coherence drives a changing coupling of the beam intensity with the observed phase. Since the randomization method deletes the CBO component of the beam motion, ω_a shifts introduced by phase drifts from the randomization method are underestimated (see Fig. 4.10). Nevertheless, since coherent betatron oscillations at calorimeters in opposite sides of the ring are out of phase by π radians, their phase drifts due to CBO de-coherence mostly cancel out [44]. The C_{pa} correction is induced by the overall detected phases around the twenty-four azimuthal locations where calorimeters accept positrons. Therefore, slowly changing detected phases from CBO de-coherence tend to cancel out. In the determination of C_{pa} central values for Run-1 datasets, the randomization method was used for this reason

Figure 4.10: ω_a shifts due to phase acceptance corrections mediated by the different phase drift extraction methods, without (left) and with (right) detector acceptance. Monte Carlo N(t) histograms are generated with the drifting phases accounted for to extract the corresponding ω_a shifts. In gray, results from the raw phase $\varphi_0^{\text{calo}13}(t)$ without drift extraction are shown. The removal of phase drifting induced by the radial CBO de-coherence from the randomized method is clearly visible in the right plot.

and the associated error from the partial cancellation was accounted for as a systematic error [44].

4.3.2 Phase drift driving mechanisms

Detected-phase distributions $\varphi_{0,k}(x_i, y_j)$ exhibit a rather consistent and symmetric pattern in x and y directions for $k = \{1, 2, ..., 24\}$ as shown in Fig. 4.7. In the radial direction, the projected phase accounting for constant, linear, and quadratic terms has an asymmetric linear trend:

$$\varphi_{0,k}(x_i) = \sum_j \varphi_{0,k}(x_i, y_j) \approx a_{x,0} + a_{x,1} x_i, \qquad (4.17)$$

whereas in the vertical case

$$\varphi_{0,k}(y_j) = \sum_i \varphi_{0,k}(x_i, y_j) \approx a_{y,0} + a_{y,2} y_i^2$$
(4.18)

the detected-phase growth is mostly quadratic around y = 0. On the beam transverse distributions side, its representative beam moments during Run-1 are largely dominated by the radial centroid and widths in both transverse directions (see Fig. 4.29). Thus, in the perspective of Eq. (4.12) and recognizing that $|\varphi_{0,k}(x_i, y_j)| \ll 1$, time dependencies of the detected phase are dominated by its coupling with the beam radial centroid and the vertical width. And as discussed in Sec. 4.3.1, phase drifts also emerge from radial CBO de-coherence.

The three dominant mechanisms that produce long-term $(30 \,\mu\text{s} < t < 700 \,\mu\text{s})$ variations of the detected phase are shown in Table 4.3.

Table 4.3: Main mechanisms of detected-phase drifts. The vertical contribution dominates the phase acceptance correction during Run-1 at calorimeters k = 13 and k = 19 near trackers longitudinal acceptance.

Mechanism	Phase drift term	$\Delta \varphi^{13,\dots}$, Run-1a sim.
Vertical beam drifts	$\varphi^{k,Y} + \Delta \varphi^{k,Y} e^{-t/\tau_{\text{Slow}}}$	$0.145\mathrm{mrad}$
Radial beam drifts	$\varphi^{k,X}$ Slow + $\Delta \varphi^{k,X}$ Slow $e^{-t/\tau}$ Slow	$0.053\mathrm{mrad}$
Radial CBO de-coherence	$\varphi^{k,X}$ CBO + $\Delta \varphi^{k,X}$ CBO $e^{-t/\tau}$ CBO	$-0.011\mathrm{mrad}$

For Run-1 cases, the phase drifts can be represented with the single-exponential functions shown in Table 4.3. The last column lists drift amplitudes by plugging $M_{T,13}$ from the COSY-based Run-1a simulated beam (see Sec. 3.6.4) at k = 13, and phase, asymmetry, and acceptance maps from GM2RINGSIM, T-Method [44]. In order to extract drifts for each mechanism individually, the distribution $M_{T,k}$ is manipulated as follows:

- Vertical (Y): Take M_{T,k}(x_{stable}, y, t), where x_{stable,i}'s are time-independent (i.e., only vertical slow drifts) and follow the radial beam distribution integrated over 30-300 μs (see Fig. 3.54).
- Radial CBO (X_{CBO}): Take $M_{T,k}(x_{CBO}, y_{stable}, t)$, where $x_{CBO,i}$'s are radial data shifted and scaled to remove mean and RMS drifts (i.e., only X_{CBO} de-coherence).

Figure 4.11 shows the resulting phases with their corresponding drifts on the right side. The de-coherence time constant τ_{CBO} is calculated from the radial CBO amplitudes decoherence and τ_{Slow} is taken to be the same for both vertical and slow-radial mechanisms.

When the entire phase drift is directly calculated from the $\varphi_0^{c_k}(t)$ signal without any manipulation of the beam distribution, the drift amplitude is in agreement within ~ 10% with the sum of the contributions from each mechanism [125], i.e.,

$$\Delta \varphi_0^k \approx \Delta \varphi^{k,Y} + \Delta \varphi^{k,X} \text{Slow} + \Delta \varphi^{k,X} \text{CBO}.$$
(4.19)

The disagreement is likely due to correlations between $\Delta \varphi^{k,Y}$, $\Delta \varphi^{k,X}$ Slow, and $\Delta \varphi^{k,X}$ CBO.

Figure 4.11: Phases $\varphi_0^{c_k}(t)$ (left) and their corresponding phase drifts (on the right) from the non-randomized, window fits method. The two plots on top correspond to a detected phase at calorimeter k = 13 from vertical beam drifting. In the middle, phase changes are driven by slow radial beam motion. At the bottom, phase drifting due to radial CBO de-coherence. Fits in red are performed to extract drift amplitudes.

4.3.3 Azimuthal extrapolation of phase drifts

Since C_{pa} corrects for detected-phase drifts at all the calorimeters and, on the other hand, beam drifts caused by the unstable optical lattice during Run-1 were azimuthally dependent (see Fig. 3.74), phase calculations of $\varphi_0^{\text{calo}\,k}$ near k = 13 and k = 19 from tracker data is not sufficient. With the detailed knowledge of the main mechanisms that drive detected-phase drifts, it is possible to prepare methods in order to project $\varphi_0^{\text{calo}\,k}$ from tracker data to all calorimeter stations $k = \{1, 2, \dots, 24\}$. The most precise method found for this end is to transform the time-dependent muon transverse coordinates $\{x(\theta_1, t), y(\theta_1, t)\}$ measured by the straw trackers one by one with the COSY-based optical lattice functions. To transform these individual coordinates from the tracker data location θ_1 to the readout azimuthal location of calorimeter k, θ_2 , a pair of equations similar to Eqs. (3.73) but with time-dependent lattice functions are used:

$$x(\theta_{2},t) = \kappa_{x}(\theta_{1},\theta_{2},t) \left(x(\theta_{1},t) - \bar{x}(\theta_{1},t)\right) + x_{0}(\theta_{2},t) + D_{x}(\theta_{2},t)\bar{\delta}$$

$$y(\theta_{2},t) = \kappa_{y}(\theta_{1},\theta_{2},t) \left(y(\theta_{1},t) - \bar{y}(\theta_{1},t)\right) + y_{0}(\theta_{2},t),$$
(4.20)

where

$$\kappa_x(\theta_1, \theta_2, t) = \frac{\sqrt{\varepsilon_x(t)\beta_x(\theta_2, t) + D_x^2(\theta_2, t)\sigma_\delta}}{\sigma_x(\theta_1)} \quad \text{and} \quad \kappa_y(\theta_1, \theta_2, t) = \sqrt{\frac{\beta_y(\theta_2, t)}{\beta_y(\theta_1, t)}}.$$
 (4.21)

All the parameters in Eqs. (4.20) and (4.21) are readily available from tracker data and the optical lattice functions for each Run-1 dataset. Shifting factors can be introduced to match offsets between closed orbits and tracker data; these discrepancies are accounted for as systematic errors of the phase acceptance correction [44]. Also, radial closed orbit drifts can be ignored (see Sec. 3.6.4) and azimuthal distortions of the vertical closed orbit can be treated as an additional systematic error since the detected phase does not strongly depend on beam vertical centroid drifts. Once beam transverse profiles $M_{T,k}(x_i, y_j, t)$ are produced in this way, Eq. (4.12) can be utilized to compute the time-dependent phases at each calorimeter station. Validation tests were performed by comparing the resulting ω_a shifts following the aforementioned method with detected phases directly computed with $M_{T,k}$ from COSY-based tracking simulations [44]. Discrepancies of less than 10 ppb were found between these two approaches, indicating reliance on the reconstructed method via Eqs. (4.20).

Another method to reproduce detected-phase drifts at each calorimeter is to scale drift amplitudes from the main phase acceptance correction driving mechanisms (see Eq. (4.19)) [125]. Although this procedure leads to a less accurate C_{pa} (~ 50 ppb), it provides a path to identify the overall effect of each driving mechanism on the final correction as shown next.

With the COSY-based Run-1a simulated beam (see Sec. 3.6.4) at $k = \{1, 2, ..., 24\}$, common phase/asymmetry maps for all calorimeter stations (for comparison purposes), and per-calorimeter acceptance maps from GM2RINGSIM (T-Method) [44], detected phases are computed via Eq. (4.12). The drift amplitudes $\Delta \varphi^{k,Y}$, $\Delta \varphi^{k,X}$ Slow, and $\Delta \varphi^{k,X}$ CBO are thereafter calculated at all calorimeter stations as explained in Sec. 4.3.2; see results in Figs. 4.12-4.14.

In the vertical case, even though the induced phase shifts are a consequence of both centroid and width drifts, the drift amplitudes are strongly dominated by vertical width changes (Fig. 4.12). This feature is evident when a reference drift, in this case at k = 13, is scaled according to the relation between vertical width shifts along the azimuth from $t = 30 \,\mu$ s to $t = 300 \,\mu$ s and the width change at k = 13 (red line). The scaling factor is prepared either from beam tracking simulations or the squared-rooted ratio between vertical

Figure 4.12: Drifting phase amplitudes from single-exponential fits to phase drifts (extracted from non-randomized, sliding window fits) induced by vertical beam motion. In red, scaling of the phase amplitude at calorimeter k = 3 with vertical beam width drifts only.

beta functions.

In a similar way, induced phase shifts in the X_{Slow} case around the ring are modulated mostly by radial centroid shifts, scaled by the time-evolving radial dispersion function. In spite of radial width changes over time due to unstable radial beta and dispersion functions (see Sec. 3.6.4), as shown in Fig. 4.13 drifts of the radial centroid are the main source of the phase drifts from this end.

The situation is different in the X_{CBO} case, where differences along the ring azimuth are induced by differences in calorimeter acceptances. By comparing Fig. 4.14 with the relative total intensity expected to be measured by calorimeters based on the COSY-based simulated beam and acceptance maps from GM2RINGSIM (see Fig. 4.15), it is concluded that beam drifts do not interfere considerably with the phase acceptance correction from radial CBO de-coherence. This statement is in agreement with the fact that the de-coherence

Figure 4.13: Drifting phase amplitudes from single-exponential fits to phase drifts (extracted from non-randomized, sliding window fits) induced by radial slow beam drifts. In red, scaling of the phase amplitude at calorimeter k = 3 with radial beam centroid drifts only.

Figure 4.14: Drifting phase amplitudes from single-exponential fits to phase drifts (extracted from non-randomized, sliding window fits) induced by radial CBO de-coherence. Variations are largely caused by calorimeter acceptances, which exhibit a characteristic azimuthal pattern owing to the instrumentation between the storage volume and the calorimeter detectors (see Fig. 4.15).

evolves equally along the storage ring.

Figure 4.15: Convolution of total intensities detected by each calorimeter (T-Method) using the COSY-based Run-1a simulated beam and GM2RINGSIM acceptance maps. The formula on the top-left corner indicates the weighting of the beam intensity with muon detection efficiency.

Figure 4.16 shows the corresponding ω_a shifts from each of the phase drifting mechanisms separately and combined. The largest contributor to the phase acceptance correction—and following the nature of detected-phase maps—is vertical width drifts over the data taking period. The independent contributions roughly combine to produce the total precession shift, and the optical lattice evolution together with the radial CBO de-coherence dictate the detected phase behavior over the azimuth.

In reality, detected-phase distributions $\varphi_{0,k}(x_i, y_j)$ depend on the calorimeter location due to material effects. Figure 4.17 is an example of the ω_a shifts derived from tracker data, the COSY-based optical lattice functions, and GM2RINGSIM per-calorimeter phase/asymmetry/calorimeter maps, where the variations of per-calorimeter maps break the symmetries displayed in Fig. 4.16.

The time-dependent optical lattice during Run-1 was the main driver of non-negligible

Figure 4.16: Relative ω_a shifts induced by each of the drifting phase mechanisms, separated and combined. The largest shifts are produced by beam drifts of the vertical width.

Figure 4.17: ω_a shifts induced by phase-acceptance drifts from experimental data (Run-1d) [44]. The Run-1d COSY-based optical lattice functions and per-calorimeter maps from GM2RINGSIM (T-Method) are utilized to calculate all the precession corrections from phase drifts extracted with the randomization method. Courtesy of Elia Bottalico.

phase acceptance corrections. Beam drifts during the measurement of ω_a were induced by the unstable lattice, and to a lower extent muon loss rates also play a role in the slowly changing vertical beam width. The faulty resistors that affected the ESQ over Run-1 datasets were repaired. Thus, phase acceptance corrections are expected to be significantly smaller during Runs 2 and beyond. The expertise developed during the analysis of the Run-1 dataset is planned to be extended for posterior runs to precisely quantify C_{pa} from radial CBO de-coherence and beam drifts induced by lost muons.

4.4 The Electric Field Correction and the Pitch Correction

The E-field C_e and pitch C_p corrections are used to counteract the biasing on ω_a due to the momentum spread and vertical betatron motion of the beam, respectively. As introduced in Sec. 1.3.3, i.e., Eqs. (1.32) and (1.33), the additional precession frequencies from the terms beyond the scope of the nominal g-2 frequency in Eq. (1.30) can be encapsulated in the standard C_e and C_p expressions:

$$C_e = \frac{n_0 \beta_0^2}{1 - n_0} 2\left< \delta^2 \right> , \qquad C_p = \frac{n_0}{2\rho_0^2} \left< y^2 \right>.$$
 (4.22)

Independent hand calculations of C_e and C_p , starting with the work of Farley [49], converge to the expressions shown in Eq. (4.22) for similar conditions characteristic to the g-2 storage ring. Nevertheless, a computationally driven approach to test the standard expressions C_e and C_p is also relevant and offers advantages when benchmarking them to the ppb level [126]. In particular, second-order effects from the nonlinear ESQ electric field, as well as asymmetric momentum spread and discrete ESQ plates, can conveniently be accounted for in the determination of the E-field and pitch corrections.

4.4.1 Methodology

With the COSY-based model, spin and orbital tracking of a realistic muon beam in the g-2 storage ring is performed. The method to extract frequencies relative to the nominal g-2 frequency

$$\Delta\omega_a\left(t'_j\right) = \omega_a\left(t'_j\right) - \omega_{a0} \tag{4.23}$$

is to compute and track muon angles $\varphi_a(t)$ per turn j around the ring. φ_a 's are defined as angles between spin and momentum vectors projected on the horizontal midplane.³ The frequencies $\omega_a\left(t'_j\right)$ are defined turn-by-turn as

$$\omega_a\left(t'_j\right) = \frac{d\varphi_a}{dt} \approx \frac{\Delta\varphi_a}{\Delta t} = \frac{\varphi_a\left(t_{j+1}\right) - \varphi_a\left(t_j\right)}{t_{j+1} - t_j}.$$
(4.24)

Unless otherwise specified, a perfectly matched beam of $N_{muons} = 128 \times 10^6$ muons with typical Run-1 experimental distributions (see Fig. 4.18) are tracked $N_{turns} = 100$ turns with the COSY-based model for these studies. Even though the real g-2 beam is mismatched to the optical lattice of the ring, the characteristic oscillations owing to the mismatch introduce equally fast oscillations to the overall spin precession frequency of the beam that cancel out during the data taking period.

The time profile of the simulated beam is shown in Fig. 3.14. To recreate similar condi-

³In reality, the measured precession frequency in the experiment results from the parity-violating observable, i.e., the phase between spin and momentum (without projections onto planes). However, the method followed in this work has been proven to recreate the nominal C_e and C_p corrections to ppb-level accuracy and previous analyses have implemented similar methods to high reliability [127].

Figure 4.18: x - a - y - b beam distributions (matched to the ring optical lattice) used in tracking simulations for $C_{e,p}$ analysis.

tions of the momentum spread, results from the fast rotation (FR) analysis for the Run-1d dataset [51] are implemented in the preparation of the simulated beam (see Fig. 1.13). The spin distribution is taken from BDS numerical results (explained in Chap. 2) at the end of the M5-line (see Fig. 2.10).

The spin and momentum vectors of each muon in the simulation are recorded every turn and individual φ_a 's computed. In this way, the overall spin precession frequency (relative to ω_{a0}) of the simulated beam is determined as

$$\left\langle \frac{\Delta\omega_a}{\omega_{a0}} \right\rangle_{\text{sim}} = \frac{1}{N_{\text{turns}} N_{\text{muons}}} \sum_{j=1}^{N_{\text{turns}} N_{\text{muons}}} \left(\frac{\Delta\omega_a\left(t'_j\right)}{\omega_{a0}} \right)_i, \quad (4.25)$$

whereas the associated statistical error of the calculation is defined from the standard error of the mean:

$$\delta \left(\Delta \omega_a / \omega_a\right)_{\text{sim}}^{stat} = \left(\frac{\Delta \omega_a}{\omega_{a0}}\right)_{SE} = \sigma \left(\frac{\Delta \omega_a}{\omega_{a0}}\right) \frac{1}{\sqrt{N_{\text{turns}}N_{\text{muons}}}}.$$
(4.26)

With the data analysis framework ROOT [128], the quantities above are processed as shown next.

To establish the resolution that can be achieved out of this method, first a muon beam without vertical motion is tracked around a ring with perfectly vertical magnetic field and the ESQ turned off (i.e., HV = 0). Under these conditions, $\Delta \omega_a = 0$ is expected for any muon. Results are shown in Fig. 4.19. The limit (10⁻³ ppb) is comparable to the precision of numbers in C + + utilized in ROOT. Similar results are obtained for $y = b = \delta = 0$ and the ESQ turned on, although in this case $\sigma (\Delta \omega_a / \omega_{a0}) \sim 3$ ppb.

4.4.2 Electric field correction C_e

With the resolution of the framework established, more realistic features can be added to simulations with the COSY-based model. To test C_e under the approximations necessary to derive it, a beam without vertical betatron motion, perfectly Gaussian momentum spread is tracked around a ring with perfect vertical magnetic field and ESQ with continuous plates covering the entire ring and only quadrupole electric field component (i.e., $a_{k,0} = 0$ for

Figure 4.19: $\langle \Delta \omega_a \rangle$ spread versus time (left) and momentum offset (right). Muons are contained in the horizontal midplane, the magnetic field is uniform and oriented in the vertical direction, and the ESQ is turned off.

k > 2). Figure 4.20 shows results for this scenario. Under these approximations,

$$-|C_e| - \left\langle \frac{\Delta \omega_a}{\omega_{a0}} \right\rangle_{sim} = 0.8 \pm 0.1 \,\mathrm{ppb.} \tag{4.27}$$

The small difference is likely caused by the curvature of the plates, since the simulation accounts up to tenth-order terms in the transfer maps. When the momentum spread distribution from FR analysis is used instead:

$$-|C_e| - \left\langle \frac{\Delta \omega_a}{\omega_{a0}} \right\rangle_{sim} = 5.2 \pm 0.1 \,\mathrm{ppb.} \tag{4.28}$$

Thus, the isolated effect of an asymmetric Run-1 style δ distribution adds a correction of ~ 4.4 ppb to C_e , which introduces higher order distribution moments (e.g., $\langle \delta^3 \rangle$) to the

Figure 4.20: $\langle \Delta \omega_a \rangle$ spread distribution (right) and versus time (left). Muons are contained within the horizontal midplane to exclude C_p . Typical frequency spreads due to the C_e correction are approximately equal to ~ 540 ppb, as observed from the standard deviation in the right plot.

momentum spread such that

$$\left\langle \frac{\Delta\omega_a}{\omega_{a0}} \right\rangle = \left\langle -\frac{e}{m} \left[\left(1 - \left(1 - \frac{1}{(1+\delta)^2} \right) \right) \frac{\beta_z E_x}{c} \right] \right\rangle$$
$$= -\left| C_e \right| + \frac{n_0 \beta_0^2}{1 - n_0} \left(1 + 2\beta_0^2 \right) \left\langle \delta^3 \right\rangle + \cdots$$
$$\neq -\left| C_e \right|. \tag{4.29}$$

In a similar manner, further features of the storage ring—not accounted for in the sensible approximations from which C_e and C_p are derived—are added in the tracking, namely, ESQ plates discretization, ESQ higher order multipole terms for all $a_{k,0}$ coefficients, and ESQ fringe fields (see Sec. 3.2.1). Table 4.4 lists all the cases of study, in addition to the beam and ring features described above (i.e., "DIEQ Ring"), and Table 4.5 shows comparisons between C_e and tracking for each of those cases.

Case label	ESQ Plates discretization	ESQ higher order multipoles	ESQ Fringe fields
DIEQ Ring			
DIEQ	Х		
DIEM	Х	Х	
DIEM-FR	Х	Х	Х

Table 4.4: Cases of study for $\langle \Delta \omega_a \rangle$ tracking, from the simple (top) to the detailed model (bottom).

Table 4.5: C_e versus tracking (no vertical betatron motion).

Case	$- C_e - \left\langle \frac{\Delta \omega_a}{\omega_{a0}} \right\rangle_{sim}$ [ppb]
DIEQ Ring	4.4 ± 0.1
DIEQ	-5.5 ± 0.1
DIEM	-9.8 ± 0.1
DIEM-FR	-7.7 ± 0.1

While tracking results indicate an overall ω_a frequency slightly higher than C_e due to an asymmetric momentum spread, the other effect pushes the discrepancy down up to 7.7 ppb. The disagreements are induced by muons with momentum offsets near the momentum acceptance of the ring, as indicated by δ -binned differentiated results.

4.4.3 Pitch correction C_p

Up to this point, no vertical motion of the beam has been considered in order to analyze C_e only, without the intrusion of C_p . Next, the attention is directed to C_p instead. For this purpose, a monochromatic beam composed of muons at magic momentum only (i.e., $\delta = 0$) is tracked down. To get closer to the initial ideas that permitted the derivation C_p , muons initially have no radial betatron motion even though an unavoidable, and small, radial motion emerges from the curvature of the ESQ plates ($E_x(x = 0, y \neq 0) \neq 0$). Nevertheless, since radial and vertical motions are mostly decoupled, the small radial motions do not

incorporate errors to the C_p versus tracking comparisons discussed next.

In this scenario and keeping perfect vertical magnetic field as well as continuous ESQ plates with a field structure originated only by the $a_{2,0}$ quadrupole coefficient (see Sec. 3.2.1), results as shown in Fig. 4.21 are obtained. In contrast to the C_e -only studies above where

Figure 4.21: $\langle \Delta \omega_a \rangle$ spread distribution (right) and versus time (left). Muons are launched with no radial motion nor momentum offsets, to exclude C_e . The frequencies spread due to the C_p correction is 0.1% as shown in the plot on the right.

individual $\Delta \omega_a$'s are spread out within a standard deviation of ~ 537 ppb, the C_p -only case exhibits typical spreads of about 0.1%. As such, the associated statistical error is larger with $N_{muons} = 128 \times 10^6$ and $N_{turns} = 100$; namely, 8.5 ppb. The comparison yields

$$-\left|C_{p}\right| - \left\langle\frac{\Delta\omega_{a}}{\omega_{a0}}\right\rangle_{sim} = -9.1 \pm 8.5 \,\mathrm{ppb.} \tag{4.30}$$

One of the main assumptions of C_p is harmonic vertical motion $(y(t) = y_0 \cos(\omega_y t + \phi_y))$. However, to satisfy Laplace's equation in curvilinear coordinates the vertical electric field that drives the oscillatory vertical motion is not purely linear. Instead, nonlinear components influence the motion as well:

$$E_y(x=0,y) = -\sum_{l=1}^{\infty} a_{0,l} \frac{y^{l-1}}{(l-1)!}.$$
(4.31)

Table 3.1 shows nonzero $a_{0,l}$'s for l = 0, 2, 4, ... due to the ESQ stations geometry. Since the tracking simulations encompass such components of the ESQ fields, C_p is not in full agreement with the tracking results (Eq. (4.30)) for which the vertical motion is not entirely harmonic.

4.4.4 Electric field and pitch corrections $C_e + C_p$

In reality, the measured precession frequency of the g-2 stored beam experiences biasing due to both effects that the C_e and C_p attempt to correct. Up to now, the comparisons between tracking simulation results and these corrections treated independently have yielded reassurance on their usage to ~ 10 ppb accuracy. The next step is to track the full beam with betatron amplitudes in both transverse directions and realistic momentum spread, as specified at the beginning of this section. The spread of $\Delta \omega_a$ is dominated by the pitch effect as shown in Fig. 4.22. Table 4.6 lists comparison results for the implemented cases.

Table 4.6: $C_e + C_p$ versus tracking (full betatron motion).

Case	$-\left C_{e}+C_{p}\right -\left\langle \frac{\Delta\omega_{a}}{\omega_{a0}}\right\rangle _{sim}$ [ppb]
DIEQ Ring	-6.4 ± 8.5
DIEQ	-8.7 ± 8.5
DIEM-FR	-10.0 ± 8.5

Due to the circular storage volume, muons with smaller vertical betatron amplitudes y_{max}

Figure 4.22: $\langle \Delta \omega_a \rangle$ spread distribution versus time of a simulated g-2 beam with Run-1 characteristics (note the logarithmic color scale). The pitch effect dominates the spread.

are allowed to have momentum offsets within the entire momentum acceptance of the ring. On the other hand, the largest y_{max} amplitudes are allowed only for $\delta \rightarrow 0$, in which case the E-field correction is minimal. This interrelation is revealed in Fig. 4.23 (left plot); muons near the midplane are more in need of an E-field correction. The beam is normally distributed in phase space; therefore, the population of muons with small y_{max} amplitudes tends to be small and results in Fig. 4.23 are weighted accordingly to compute the total precession frequency of the beam.

4.4.5 Run-1 considerations

During Run-1, both the field index (Fig. 4.24), defined in Eq. (3.26), and radial dispersion function (Fig. 3.71) drifted during the data taking period. As a consequence, the ensemble of momentum-dependent radial closed orbits $x_e = x_0 + D_x \delta$ slowly varied over time as well.

Figure 4.23: $\langle \Delta \omega_a \rangle$ spread binned over vertical betatron amplitudes (left) and momentum offsets (right) for the case of full betatron motion.

Figure 4.24: Effective field indices over time during Run-1 from straw trackers data $(n_0 = 1 - \left[1 - \omega_{CBO,x}/2\pi f_c\right]^2)$.

Moreover, tracking simulations with the COSY-based model indicate a slightly changing momentum spread distribution due to lost muons $(\Delta \bar{\delta}(30 \,\mu s \rightarrow 300 \,\mu s)/\bar{\delta}(30 \,\mu s) \approx 0.25\%$ and $\Delta \delta_{RMS}(30 \,\mu s \rightarrow 300 \,\mu s)/\delta_{RMS}(30 \,\mu s) \approx 0.4\%)$. By taking one of the intermediate expressions involved in the derivation of the standard E-field correction, see Eq. (4.22), such effects can be analyzed as follows [129]:

$$C_e(t) = 2 \frac{n_0(t)\beta_0^2}{\rho_0} \langle x_e(t)\delta(t) \rangle_{N,\varphi} \Rightarrow C_e(t) = 2 \frac{n_0(t)\beta_0^2}{\rho_0} \left[\langle D_x(t) \rangle_{\varphi} \left\langle \delta(t)^2 \right\rangle_N + \langle x_0(t) \rangle_{\varphi} \left\langle \delta(t) \rangle_N \right],$$

$$(4.32)$$

where $\langle \rangle_N$ denotes average over the muon bunch and $\langle \rangle_{\varphi}$ are azimuthal averages along the ring with ESQ occupancy. The momentum-independent closed orbit x_0 was not significantly affected by the changing electric fields, thus its contribution to a changing C_e is negligible. Figure 4.25 shows how the temporary C_e changes due to the dynamic effects of Run-1, relative to the normal calculation of the correction C_{e0} ($\Delta C_e = C_{e0} - C_e(t)$). To estimate the entire effect over each Run-1 dataset due to the time-evolving ω_a from changing electric fields and momentum distribution, results shown in Fig. 4.25 are incorporated into Monte Carlo simulations similar to the method followed in Sec. 4.2 to extract C_{ml} but, instead of a manipulation of φ_0 , the spin precession frequency ω_a is directly defined as $\omega_a(t) =$ $\omega_{a0}(1 - C_e(t))$. Table 4.7 lists deviations from time-independent C_e corrections; all of which are found to be small compared to the main systematic corrections of C_e during Run-1 [45]. The effect of changing vertical beam widths on C_p has also been studied with β_y from the COSY-based model functions [104] and found to be small (~ 1 ppb).

In conclusion, this analysis has tested the robustness of C_e and C_p and indicates that the asymmetric momentum spread, discrete ESQ plates, nonlinear ESQ fields and its fringe fields introduce a systematic correction of -10.0 ± 8.5 ppb to the standard C_e+C_p formalism

Figure 4.25: Temporal $C_e(t)$ corrections (relative to the time-independent case) during Run-1 under the effects of changing momentum spread and time-dependent ESQ electric fields.

used in the experiment.

4.5 The Weighted Magnetic Field \tilde{B}

The driver of the muon beam rotational polarization around its momentum direction is the

magnetic field of the g-2 storage ring. Subject to the spatial distribution of the muon beam

Table 4.7: Deviations to time-independent C_e corrections during Run-1, based on tracking simulations and optical lattice calculations with the COSY-based model of the g-2 storage ring.

	$\Delta C_e \text{ [ppb]}$
Run-1a (60h)	-0.24 ± 0.013
Run-1b (HK)	-2.76 ± 0.011
Run-1c $(9d)$	-3.68 ± 0.014
Run-1d (EG)	-2.50 ± 0.012

during the data taking period, the measured anomalous magnetic moment of the muon is proportional to the ratio between the g-2 frequency ω_{a0} and the total field \tilde{B} experienced by the beam. In spite of the high uniformity of the magnetic field in the ring's storage volume (i.e., $|\vec{B}| = B \approx B_y$ to $\mathcal{O}(10 \text{ ppb})$ accuracy [39]), its ppm-level localized variations along the ring azimuth can couple to the azimuthal behavior of the stored beam. At the previous muon g-2 experiment at BNL, the error budget of their a_{μ} measurement allowed to safely calculate the averaged field \tilde{B} without the consideration of the beam azimuthal variations [8]. However, a consideration of such beam variations is required for the muon weighting of the magnetic field to be determined to a precision of 10 ppb or less [46] and in this way achieve the precision goals of the muon g-2 experiment at Fermilab.

For this purpose, a method to perform the muon weighting necessary to obtain B while accounting for beam azimuthal variations based on straw tracking detectors data [38] and optical lattice functions (see Sec. 3.6.2) has been developed [106] and is presented in this section. The method, which allows computing muon-weighted magnetic fields in an orderly manner, has been implemented as part of the Run-1 magnetic field analysis. Systematic errors associated with the method (e.g., detection acceptance and alignment) have been analyzed in detail and documented in [106] and are not studied in this dissertation.

To benchmark the aforementioned method, a muon-weighted field B_{orig} is prepared (see Sec. 4.5.1) via nonlinear simulations with the magnetic field in the COSY-based model from trolley data, where the beam distribution is tracked at several azimuthal locations of the ring. With these results as reference, the method to reconstruct \tilde{B}_{orig} out of information of the beam transverse intensity at one azimuthal location (named \tilde{B}_{recon}) presented in Subsec 4.5.2 is validated as shown in Sec. 4.5.3. Lastly, sensitivity studies to understand the dependence of the muon-weighted field calculation on specific azimuthal variations of the stored beam are discussed.

4.5.1 The muon-weighted field \tilde{B} from the simulated beam

Ideally, to capture the coupling between field and beam distortions along the storage ring azimuth in the muon weighting of the magnetic field $B(x, y, \theta)$, it is weighted by the timeand azimuth-dependent muon transverse intensity $M_T(x, y, \theta, t)$ throughout the data taking period [39]:

$$\tilde{B} = \int_{t_0}^{t_f} \int_x \int_y M_T(x, y, \theta, t) B(x, y, \theta) dx dy d\theta dt',$$
(4.33)

where θ is the azimuthal angle, x and y the radial and vertical coordinates, t is the time where t = 0 coincides with beam injection into the ring, and the beam intensity is normalized:

$$\int_{t_0}^{t_f} \int_x \int_y M_T(x, y, \theta, t) dx dy dt' = 1.$$
(4.34)

However, the azimuthal gradients of the optical lattice functions (including closed orbits) in the ring with rather weak vertical focusing and the resolution of tracker experimental data are small enough to conveniently consider a discrete summation instead:

$$\tilde{B} = \frac{1}{N} \sum_{i=1}^{N} \tilde{B}_{i} = \frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{N} \sum_{k=1}^{N} \sum_{k=1}^{N} M_{T} \left(x_{j}, y_{k}, \theta_{i} \right) B_{i} \left(x_{j}, y_{k} \right), \qquad (4.35)$$

where

$$\sum_{j}^{N_x} \sum_{k}^{N_y} M_T\left(x_j, y_k, \theta_i\right) = 1$$
(4.36)

and

• N: Number of azimuthal slices.

- N_x : Number of x bins.
- N_y : Number of y bins.
- $M_T(x_j, y_k, \theta_i)$: Binned transverse beam profile at θ_i integrated over 30 µs < t < t_f .⁴
- $B_i(x_j, y_k)$: Binned magnetic field map at *i*-th azimuthal slice, averaged within $\left[\theta_i \frac{\pi}{N}, \theta_i + \frac{\pi}{N}\right]$.

Although N = 72 in practice [106], the number of azimuthal slices is equal to 24 for the following analysis, which has been found to be sufficient for incorporating azimuthal dependencies in \tilde{B} .

In order to obtain the B_{orig} introduced above for the validation of the reconstruction method (see Sec. 4.5.2 and 4.5.3), tracking simulation results for the Run-1a dataset are used. Figure 4.26 shows all the $M_T(x_j, y_k, \theta_i)$ beam profiles at the 24 locations of interest, centered at the regions of maximum azimuthal sensitivity per calorimeter detector.

Each of the transverse profiles in Fig. 4.26 are combined with their corresponding magnetic field slice $B_i(x_j, y_k)$ —shown in Figs. 4.27 and their azimuthal variations in Fig. 3.8—to calculate \tilde{B}_{orig} .

Figure 4.28 shows \tilde{B}_i at their corresponding θ_i azimuthal locations. The muon-weighting is dominated by the dipole field contribution (compare Fig. 4.28 with c_0 in Fig. 4.30). To identify the main contributions in terms of multipole coefficients, the azimuthally binned muon-weighted field maps are expressed as follows (similar to Eq. (3.8)):

$$\tilde{B}_{i} \approx B_{0} \left(1 + c_{0,i} + \sum_{n=1}^{4} \left[c_{n,i} I_{n,i} + s_{n,i} J_{n,i} \right] \right), \tag{4.37}$$

⁴For the purposes of this section, $t_f = 300 \,\mu\text{s}$. In the experiment, $t_f \approx 700 \,\mu\text{s}$. And for Run-1d, the initial time was 50 μ s instead of 30 μ s.

Figure 4.26: Run-1a simulated beam transverse profiles $M_T^{orig}(x_j, y_k, \theta_i)$, integrated over $30 \,\mu\text{s} < t < 300 \,\mu\text{s}$. The 24 azimuthal locations coincide with the regions of maximum calorimeter detection acceptance. Horizontal and vertical axes correspond to $-60 \,\text{mm} < x < 60 \,\text{mm}$ and $-60 \,\text{mm} < y < 60 \,\text{mm}$. Refer to Fig. 4.36 for the color legend.

Figure 4.27: Magnetic field maps $B_i(x_j, y_k)$ from trolley run number 3956 (close to the Run-1a data period). The azimuthal locations of each map correspond to the beam profile azimuths arrangement in Fig. 4.26. Field intensities are shown for $\sqrt{x^2 + y^2} < 45$ mm, where the horizontal and vertical axes are x and y, respectively. Each color represents a particular magnetic field magnitude to illustrate polar uniformities.

Figure 4.28: \tilde{B}_i magnetic fields (trolley run 3956) weighted with the Run-1a simulated beam at 24 azimuthal locations.

where $B_0 = p_0/e\rho_0$ is the ideal field to sustain magic momentum muons at $p_0 \approx 3.094 \,\text{GeV/c}$.

$$I_{n,i} = \sum_{j,k} M_T \left(x_j, y_k, \theta_i \right) \left(\frac{r \left(x_j, y_k \right)}{r_0} \right)^n \cos \left[n\phi \left(x_j, y_k \right) \right]$$

$$J_{n,i} = \sum_{j,k} M_T \left(x_j, y_k, \theta_i \right) \left(\frac{r \left(x_j, y_k \right)}{r_0} \right)^n \sin \left[n\phi \left(x_j, y_k \right) \right]$$
(4.38)

are the normal, $I_{n,i}$, and skew, $J_{n,i}$, multipole beam projections (see Fig. 4.29). In Eq. (4.38), $r_0 = 4.5 \text{ cm}$ is the normalization radius, $r = \sqrt{x^2 + y^2}$ the transverse radius relative to the reference orbit, and ϕ the polar angle such that $x = r \cos \phi$ and $y = r \sin \phi$. The normal, $c_{n,i}$, and skew, $s_{n,i}$, magnetic multipole terms in Eq. (4.37) at each of the $B_i(x_j, y_j)$ maps are shown in Fig. 4.30.

The contribution of each $n \ge 1$ magnetic multipole to the muon-weighted field is strongly

Figure 4.29: Multipole beam projections $\{I_{n,i}, J_{n,i}\}$ versus order *n* from the Run-1a simulated beam (Similar projections are observed in the other Run-1 datasets). Projections of the same order and different azimuthal locations group together in the plot.

Figure 4.30: Magnetic field multipoles averaged out every 15° (trolley run 3956). Refer to Eq. (4.37).

dictated by the $\{I_{n,i}, J_{n,i}\}$ multipole beam projections:

$$\tilde{B} = \frac{1}{N} \sum_{i=1}^{N} \tilde{B}_{i} = B_{0} \left(1 + \langle c_{0} \rangle \right) + B_{0} \sum_{n=1}^{4} \left(\langle c_{n} I_{n} \rangle + \langle s_{n} J_{n} \rangle \right).$$
(4.39)

In Fig. 4.31, the weighted field contributions from each beam projection $\{\langle c_n I_n \rangle, \langle s_n J_n \rangle\}$ are shown.

Figure 4.31: Weighted field contributions from beam projections $\{\langle c_n I_n \rangle, \langle s_n J_n \rangle\}$ versus order *n* from the Run-1a simulated beam and magnetic field based on trolley run 3956.

Due to the overall radial off-centering of the beam caused by the nonzero average of its momentum spread, the normal quadrupole beam projection plays an important role in the muon-weighting of the field. Similarly, the beam widths couple with the magnetic normal sextupole term via its normal sextupole projection. On the other hand, the beam is significantly more centered in the vertical than in the radial direction; the vertical closed orbit is expected to be within 1 mm from the horizontal midplane during the data taking period due to inhomogeneities in the skew dipole term of the magnetic field (also known as the *radial magnetic field* within the muon g-2 collaboration). Therefore, skew quadrupole beam projections weakly interfere with the muon-weighting. Uncertainties from tracker and ESQ misalignments are the main sources of systematic error in the muon weighting during Run-1 (~ 13 ppb and ~ 5 ppb, respectively) [39, 106].

Even though the radial and vertical motion are highly decoupled, small correlations driven by the skew quadrupole component of the fields introduce a small contribution to \tilde{B} . The validations discussed in Sec. 4.5.3 indicate that such contributions are negligible from the magnetic field inhomogeneities side. However, it would be appropriate to assess the effects of radial-vertical coupling from ESQ misalignments (e.g., nonzero ESQ roll angles).

Lastly, Higher order beam projections of the typical g-2 stored beam are not relevant for the calculation of \tilde{B} (see Fig. 4.31). The aforementioned features are observed in Fig. 4.32.

With the relevant beam projections identified (mainly affected by centroids and widths) for the muon-weighted magnetic field in the storage ring, a method to calculate \tilde{B} based on tracker data at one azimuthal location and lattice functions is developed and presented next.

4.5.2 Method to calculate \tilde{B} from experimental data

In the experiment, transverse beam profiles $M_T(x, y, \theta_{Tr})$ are available at the two azimuthal regions where straw tracking detectors are located (see Fig. 1.11). FR analysis reconstructs momentum spread distributions [51] and lattice functions are calculated from the COSYbased model (see Sec. 3.3.2) based on magnetic field measurements [39]. With these available ingredients, beam profiles $M_T(x, y, \theta_i)$ can be reconstructed by "shifting" and "scaling" $M_T(x, y, \theta_{Tr})$ at any azimuthal location θ_i [130] as illustrated in Fig. 4.33.

First, $M_T(x, y, \theta_{Tr})$ is shifted in proportion to the radial and vertical closed orbits:

$$\Delta_x = x_0 \left(\theta_i\right) - x_0 \left(\theta_{Tr}\right) \text{ in } x,$$

$$\Delta_y = y_0 \left(\theta_i\right) - y_0 \left(\theta_{Tr}\right) \text{ in } y.$$
(4.40)

Figure 4.32: Multipole beam projections $\{I_{n,i}, J_{n,i}\}$ versus azimuthal angle from the Run-1a simulated beam.

Figure 4.33: Flow chart of the method to reconstruct \tilde{B} from experimental data and the optical lattice. With this input, beam transverse profiles $M_T(x, y, \theta_i)$ are methodically prepared in the experiment. Tracker data input on the left of the chart refers to the beam transverse profiles measured by the muon g-2 straw tracking detectors [38].

The resulting profile $M_T(x + \Delta_x, y + \Delta_y, \theta_{Tr})$ is scaled by

$$s_{x} = \frac{x_{RMS}(\theta_{i})}{x_{RMS}(\theta_{Tr})} = \sqrt{\frac{a_{x}\beta_{x}(\theta_{i}) + bD_{x}^{2}(\theta_{i})}{a_{x}\beta_{x}(\theta_{Tr}) + bD_{x}^{2}(\theta_{Tr})}} \text{ in } x,$$

$$s_{y} = \frac{y_{RMS}(\theta_{i})}{y_{RMS}(\theta_{Tr})} = \sqrt{\frac{\beta_{y}(\theta_{i})}{\beta_{y}(\theta_{Tr})}} \text{ in } y$$
(4.41)

where $a_{x,y} = \varepsilon_{x,y}^{Tr}$ are transverse emittances (see Sec. 3.3.2) defined from $M_T(x, y, \theta_{Tr})$ via

$$x_{RMS}^2\left(\theta_{Tr}\right) \approx \varepsilon_x^{Tr} \beta_x\left(\theta_{Tr}\right) + bD_x^2\left(\theta_{Tr}\right) \quad , \quad y_{RMS}^2\left(\theta_{Tr}\right) \approx \varepsilon_y^{Tr} \beta_y\left(\theta_{Tr}\right) \tag{4.42}$$

and $b = \delta_{RMS}^2$ (i.e., the beam momentum spread squared) is taken from an external analysis (e.g., FR analysis [51]). In this way, $M_T(x, y, \theta_i)$ is reconstructed:

$$M_T^{reco}\left(x, y, \theta_i\right) = M_T\left(s_x\left(x + \Delta_x\right), s_y\left(y + \Delta_y\right), \theta_{Tr}\right).$$

$$(4.43)$$

Figure 4.34 shows the resulting beam profiles where $M_T(x, y, \theta_{Tr})$ prepared from the Run-1a COSY-based simulation and the optical lattice functions are prepared with the corresponding field settings in the COSY-based model (see Sec. 3.6.2). Although lattice functions slowly changed over time during Run-1, only their values at $t = 94 \,\mu\text{s}$ (the mean time of the data taking period, accounting for muon decays) were used. The validity of this method, practical at a run level for the calculation of the muon-weighted magnetic field, is discussed next.

4.5.3 Method validation

Perfect reconstruction of the beam profiles is achieved with the "shift/scale" method if

$$M_T^{reco}\left(x, y, \theta_i\right) = M_T^{orig}\left(x, y, \theta_i\right), \qquad (4.44)$$

where M_T^{orig} are the original intensity profiles from tracking simulation results (see Sec. 4.5.1). Figure 4.35 shows a comparison of centroids and widths, which are the essential beam moments for the magnetic field average by the muon beam distribution around the ring azimuth. Disagreements between reconstructed and original distributions in the vertical direction are below 0.02 mm, whereas in the radial case the more evident discrepancies are intrinsic to the method; for the analysis of Run-2 and beyond, an upgraded method to reconstruct beam profiles for the field muon-weighting is under development, which would follow more closely Eq. (3.73). Figure 4.36 displays azimuthally averaged beam profiles from the simulated (original) and reconstructed beam. Differences between the two cases are better observed in Fig. 4.37, owing to not transforming properly the higher order beam moments with the reconstruction method.

Notwithstanding the differences between reconstructed and original profiles, the result-

Figure 4.34: Run-1a reconstructed beam transverse profiles $M_T^{reco}(x_j, y_k, \theta_i)$, integrated over 30 µs < t < 300 µs. The 24 azimuthal locations coincide with the regions of maximum calorimeter detection acceptance. Horizontal and vertical axes correspond to -60 mm < x < 60 mm and -60 mm < y < 60 mm. Refer to Fig. 4.36 for the color legend.

Figure 4.35: Time-integrated beam centroids and widths over the azimuthal angle. Red markers correspond to reconstructed beam profiles $M_T^{reco}(x, y, \theta_i)$, whereas entries from the simulated beam profiles $M_T^{orig}(x, y, \theta_i)$ are shown in black.

ing muon-weighted field \tilde{B}_{reco} reliably reproduces the original case \tilde{B}_{orig} throughout the azimuth, as shown in Fig. 4.38. The larger variations at 335° and 25° are caused by the less uniform magnetic fields at the inflector and magnet leads, respectively. In spite of these two regions, the reconstructed weighted field resembles the real case to high accuracy:

$$\frac{\tilde{B}_{reco} - \tilde{B}_{orig}}{\tilde{B}_{orig}} = -1.2 \,\mathrm{ppb} \tag{4.45}$$

An assessment of the differences from the perspective of weighted field contributions from multipole beam projections (reconstructed versus original distributions) over the azimuth is shown in Figs. 4.39 and 4.40, respectively. With all the weighted projections below 1 ppb and the lower order beam moments satisfactorily transformed, the method is validated for its use with experimental data as part of the field analysis. Since the simulated beam accounts

Figure 4.36: Reconstructed $M_T^{reco}(x, y)$ (left) and original $M_T^{orig}(x, y)$ (right) beam transverse profiles azimuthally averaged and integrated in time (30 µs < t < 300 µs).

for nonlinearities from both the electric and magnetic fields in the storage ring, it is also concluded that their effect on the beam distribution around the ring for the magnetic field muon-weighting is negligible.

4.5.4 Sensitivity of \tilde{B} to azimuthal beam variations

The versatility of the method allows performing sensitivity studies of the azimuthal beam behavior on the reconstructed field \tilde{B}_{reco} . Centroid variations from closed orbit distortions and width modulations from dispersion and beta functions characteristic to the ring's optical lattice have different consequences on the resulting \tilde{B} as shown in Table 4.8.

It is found that although the beam width (and vertical centroid) azimuthal dependence can be ignored while maintaining the reconstructed muon-weighted field to $\mathcal{O}(2 \text{ ppb})$ accuracy, the behavior of the radial centroid along the ring must be accounted for in order to

Figure 4.37: Difference between reconstructed $M_T^{reco}(x, y)$ and original $M_T^{orig}(x, y)$ beam transverse profiles azimuthally averaged and integrated in time (30 µs < t < 300 µs). Higher order beam moments unaccounted-for in the method to reconstruct profiles M_T^{reco} introduce discrepancies with the reference case M_T^{orig} .

Figure 4.38: Relative differences between reconstructed and original muon-weighted fields $(\tilde{B}_{i,reco} - \tilde{B}_{i,orig})/\tilde{B}_{i,orig}$ over the azimuthal angle. Largest discrepancies emerge at azimuthal regions where the field is less uniform (i.e., at 335° and 25° around the inflector and magnet leads, respectively).

Figure 4.39: Comparison of weighted field contributions from each magnetic multipole moment using beam projections from the reconstructed versus the original muon distribution.

Table	• 4.8:	Sensitivity	studies of	of the	muon-weighted	field	to azimuth	al	beam	variations

No vertical centroid shifting	$\Delta_y = 0$	-0.6
No radial width scaling	$s_x = 1$	-1.8
No vertical width scaling	$s_y = 1$	-1.7
No shifting/scaling	$\Delta_x = \Delta_y = 0, s_x = s_y = 1$	$-13.6\mathrm{ppb}$

satisfy the precision goals of the muon g-2 experiment. Unless the beam is better centered in the radial direction and radial closed orbits from the normal dipole inhomogeneities of the magnetic field are under control, the coupling between the normal quadrupole beam projection and the normal quadrupole magnetic field term must be considered for an accurate calculation of \tilde{B} .

For sensitivity studies specific to Run-1, the time evolution of the optical lattice was ignored in the reconstruction method to quantify their effect on the muon-weighting, which was estimated to introduce an error of ~ 1.4 ppb. Time variations of \tilde{B} due to beam drifts bias the measured ω_a frequency and, together with the lattice functions from the COSYbased model, were estimated (outside the work of this dissertation) to be negligible [106].

Figure 4.40: Multipole beam projections $\{I_{n,i}, J_{n,i}\}$ versus azimuthal angle from the Run-1a simulated beam (semi-transparent colors) and reconstructed profiles (solid colors). The small contributions from the skew octupole and decapole projections are not well transformed in the reconstruction.

4.6 Conclusions

The beam characterization developed with the COSY-based model of the storage ring and documented in Chap. 3 was directly applied to quantify systematic corrections and their uncertainties driven by beam dynamics effects in the muon g-2 experiment.

The computational derivations of the Run-1 muon loss corrections via symplectic tracking agreed with data-driven results to within 12 ppb, showing the robustness of the experimental technique utilized to derive C_{ml} from observations. The understanding of betatron resonances, tune shifts, and the data-driven implementation of magnetic fields and the ESQ behavior during Run-1 set the stage to reach confidence in the symplectic tracking results.

Methods to extract phase acceptance corrections from detected-phase drifts, identification of the main driving mechanisms of C_{pa} , and accurate procedures to calculate this correction based on the beam behavior along the entire storage ring were developed and tested for their further use with experimental data. With the time-dependent optical lattice reconstructed from tracker data, beam drifts around the ring azimuth are well understood and recreated for the determination of the phase acceptance correction during Run-1 datasets.

The standard corrections used in the muon g-2 experiment to define the E-field and pitch corrections were tested under effects not directly accounted for in their derivation, such as nonlinear ESQ electric fields, fringe fields, and segmented ESQ plates. A systematic correction of -10 ± 8.5 ppb from these effects was quantified in relation to the standard C_e and C_p corrections, which in total were equal to 489(53) ppb and 180(13) ppb, respectively, during Run-1 [45]. Specific to Run-1 conditions in the storage ring, the effect of the unstable optical lattice on C_e was established to be negligible compared to the overall size of this correction. And lastly, the optical lattice framework permitted the development of a method that accounts for the azimuthal behavior of the beam to calculate on a run-by-run basis the muonweighted magnetic field, which is important for the determination of a_{μ} from measurements. Tests with the simulated Run-1a beam from the COSY-based model validates the method. Also, it was determined that for typical Run-1 beam distributions and magnetic fields, the dominant coupling that needs to be accounted for in the muon-weighting of the magnetic field along the azimuth emerges from the radial centroid, which contributes to the total \tilde{B} about 12 ppb relative to the main value. Minimizing field inhomogeneities of the magnetic normal dipole term and centering the beam closer to the magic momentum is expected to alleviate the dependence of the field muon-weighting on the radial beam centroid.

Chapter 5

Conclusions

The objective of this dissertation was to develop a detailed characterization of the beam dynamics in the Muon g-2 Experiment at Fermilab (E989), with the goal of constraining effects intrinsic to the beam motion on the final measurement of the experiment. To that end, several methods and data-driven computational models were produced to analyze the evolution of the beam along the Muon Campus and, with more depth, inside the g-2 storage ring.

Chapter 1 covered the theoretical and experimental efforts aimed at resolving the value of the anomalous magnetic moment a_{μ} to unprecedented precision. In relation to the experimental technique of E989, the beam dynamics requirements that are necessary to achieve the experimental goals were presented, and the work described in the subsequent chapters of this document aimed at addressing them to contribute with the high-precision experimental determination of a_{μ} . At the time of this dissertation, the discrepancy between a_{μ} from theory and experiment had a significance of 4.2σ . However, both the muon g-2 experiment at Fermilab and the theory initiative still plan to keep refining their values in order to either declare the existence of physics beyond the Standard Model or to further validate the fundamental knowledge provided by this model.

In Chap. 2, the modeling of the beam delivery system (BDS) as part of this dissertation was presented. Results derived from this analysis served to validate the other models of the Muon Campus within the muon g-2 collaboration. Numerical studies of the muon beam polarization from pion decays were performed, as well as an analysis of the impact of non-linearities of the guide fields along the BDS on the muon population downstream from the pion production target. In particular, the studied effects of nonlinearities on the g-2 phase—important for beam dynamics corrections on the measured anomalous precession frequency ω_a —suggest further investigation of the momentum-phase correlation in relation to the fringe fields of the multiple rectangular magnets inside the Delivery Ring are appropriate.

In Chap. 3, the COSY-based model together with complementary methods to characterize the beam dynamics in the muon g-2 storage ring were presented. These tools were developed based on experimental data, optimization techniques, and the DA framework within COSY INFINITY. Linear and nonlinear beam dynamics were accounted for in order to recreate all the conditions that the stored muon beam experiences while ω_a is measured. The model provided an understanding of the optimal configurations of the storage ring during data taking. With a detailed implementation of the electric and magnetic fields in the model, nonlinear effects such as betatron tune shifts and resonances were characterized, which allowed for the detailed beam dynamics systematic corrections and uncertainties on a_{μ} presented in Chap. 4. Available beam diagnostics from the straw tracking detectors and high-voltage scans of the ESQ system permitted to benchmark results from the COSY-based model via symplectic tracking simulations. In particular, the reconstruction of the unstable ESQ guide fields during Run-1 and a detailed description of the optical lattice allowed to quantify the beam behavior along the storage ring azimuth under these special circumstances; from this characterization and further extensive analysis within the muon q-2 collaboration [45], beam dynamics corrections for the measured frequency ω_a were determined to high precision. In addition, the specific time-momentum correlations of the stored muon beam owing to the injection process were recreated with the model, which contributed to discover and quantify the largest systematic error of the E-field correction. The work presented in Chap. 3 took place during the commissioning and first data collection and analysis period (Run-1) of E989, although it is expected to continue to be utilized for the data analysis of the experiment (i.e., Run-2 to Run-5).

Direct applications derived from the work presented in Chap. 3 to quantify corrections (and their systematic uncertainties) of ω_a and the convoluted magnetic field are elaborated in Chap. 4. Muon loss corrections C_{ml} during Run-1 were recreated from symplectic tracking simulations with the COSY-based model, with results comparable to the data-driven quantifications (< 12 ppb). Even though muon loss corrections are expected to be negligible for Run-2 and beyond thanks to improved beam injection, the replacement of the resistors that were found to be damaged during Run-1, more collimators inserted, temperature control, and an ESQ setpoint further from betatron resonances, detailed simulations of muon loss rates would contribute diagnosing the storage ring conditions during data taking.

With the detailed description of the beam around the ring from Chap. 3, a detailed study of the phase acceptance correction C_{pa} during Run-1 was performed. Methods to extract this correction, as well as the understanding of the mechanisms that induce C_{pa} due to the beam motion around the storage ring were developed. Similar to the C_{ml} correction, the phase acceptance correction is expected to be considerably smaller during Runs 2–5 thanks to a stable ESQ system, although the precision goals of E989 would demand to evaluate this correction and its associated systematic uncertainties for all the runs.

In relation to the E-field (C_e) and pitch (C_p) corrections, the applicability for their usage in E989 was tested under several characteristic scenarios of the g-2 beam storage ring (i.e., asymmetric momentum spread, segmented ESQ stations, and ESQ nonlinear fields). A correction originated by those specific features was found to be small $(-10 \pm 8.5 \text{ ppb})$. The time-evolving ESQ electric fields during the Run-1 ω_a measurement were found to not affect the E-field correction in a significant way. As a next step, the effect of nonlinearities (e.g., betatron amplitude modulations) and closed orbit distortions from magnetic field inhomogeneities on the E-field and pitch corrections could be analyzed with the COSY-based model, which could become relevant due to the proximity of the operational ESQ setpoint to the resonant condition $3\nu_y = 1$ during Runs 2–5.

And lastly, a method for weighting the magnetic field with the stored muon beam along the azimuth of the storage ring was discussed. Validations with tracking simulations indicated reliance for its further use with experimental data. Sensitivity studies determined that, due to the specific transverse beam profile in E899 measured by the straw tracking detectors, azimuthal dependencies of the beam radial centroid are essential to be accounted for in the field weighting to estimate this quantity to parts-per-billion precision. Based on this work, it can be concluded that further improvements of the beam injection process which drive the radial centroid of the stored beam closer to the design orbit (as in the case of Run-2 and beyond) would lead to a muon-weighting of the magnetic field less dependent on the beam azimuthal behavior.
