

INFORMATION TO USERS

This reproduction was made from a copy of a document sent to us for microfilming. While the most advanced technology has been used to photograph and reproduce this document, the quality of the reproduction is heavily dependent upon the quality of the material submitted.

The following explanation of techniques is provided to help clarify markings or notations which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting through an image and duplicating adjacent pages to assure complete continuity.
2. When an image on the film is obliterated with a round black mark, it is an indication of either blurred copy because of movement during exposure, duplicate copy, or copyrighted materials that should not have been filmed. For blurred pages, a good image of the page can be found in the adjacent frame. If copyrighted materials were deleted, a target note will appear listing the pages in the adjacent frame.
3. When a map, drawing or chart, etc., is part of the material being photographed, a definite method of "sectioning" the material has been followed. It is customary to begin filming at the upper left hand corner of a large sheet and to continue from left to right in equal sections with small overlaps. If necessary, sectioning is continued again—beginning below the first row and continuing on until complete.
4. For illustrations that cannot be satisfactorily reproduced by xerographic means, photographic prints can be purchased at additional cost and inserted into your xerographic copy. These prints are available upon request from the Dissertations Customer Services Department.
5. Some pages in any document may have indistinct print. In all cases the best available copy has been filmed.

ABSTRACT

COMMUNITY METABOLISM AND AUTOTROPHIC-HETEROTROPHIC RELATIONSHIPS OF WOODLAND STREAM RIFFLE SECTIONS.

By

Donna Kay King

Using an in situ chamber oxygen method at five first through third order riffle sites in Augusta Creek, Michigan, estimates of community metabolism were made on a monthly or seasonal basis (1973 - 1975). Combined site, net community productivity (NCP) ranged from -0.25 to 4.03 g O₂ m⁻²d⁻¹, community respiration (CR) from 0.24 to 3.67 g O₂ m⁻²d⁻¹, and gross community productivity (GCP) from 0.09 to 5.35 g O₂ m⁻²d⁻¹. The integrative parameters net daily metabolism (NDM) and ratio of GCP to 24 hour CR (P/R) ranged from -0.72 to 2.68 g O₂ m⁻²d⁻¹ and -0.017 to 2.5, respectively and remained constant at each site.

Most parameters were consistently low and stable at first order sites, while autotrophic sites varied significantly. Light-saturated photosynthesis occurred between 15,000 to 24,000 lux; no photoinhibition was evident.

Detrital standing crops were stable at each site and ranged from 146 to 592 g m⁻². Average ratio of coarse to fine particulate organic matter ranged from 0.12 to 0.4 with an inverse relationship with P/R. Epilithon values ranged from 1480 to 5030 g m⁻². Detritus averaged 12% of the total particulate organic matter. Epilithon was detrital based at first order riffles; other sites were algal dominated.

Average ratio of epilithon to detritus ranged from 4.5 to 14.8 with greatest seasonal differences at the autotrophic sites.

Stream order was most highly correlated with all dependent variables (NCP, CR, GCP, NDM) followed by light. Temperature and epilithon development were significantly correlated with all dependent variables; non-attached detritus had little correlation.

Particle-sized sediment (4 mm, 1 mm, 250 μm , 75 μm , 0.45 μm) contributions to NCP and CR were highest on 0.45 μm detritus and 4 mm (NCP) and 75 μm (CR) inorganic sediments on an AFDW basis. Areal estimates indicated highest NCP on larger inorganic and organic particles; highest CR occurred on 0.45 μm detritus and 4 mm inorganic particles. CR was highest on all detrital fractions on an AFDW basis; epilithon had higher contributions to NCP and CR on an areal basis. In situ trends were similar to areal particle-sized estimates. The support of woodland stream riffle sections was dependent on epilithon development while the autotrophic-heterotrophic balance was dependent upon the floral composition.

This work is dedicated to Matthew H. Hohn.
Who introduced me to the finer (diatomaceous) things of life.

ACKNOWLEDGEMENTS

I would like to express sincere appreciation to Ken Cummins, for the atmosphere created in his laboratory, which allowed a technician to "sprout" into a student. His flexibility, enthusiasm, encouragement and friendship are valued. I am also grateful for the Montana "experience" and the opportunity to participate in the comparative methods conference at the Stroud Water Research Laboratory; both were highlights while working on this degree.

This study would not have been completed without the continued interest and support of my guidance committee: Drs. Kenneth W. Cummins, Chairman; Niles R. Kevern; Michael J. Klug; Robert G. Wetzel; and Matthew H. Hohn. To each I am grateful for their contributions to the thesis and my education. Dr. George H. Lauff, Director of the Kellogg Biological Station, deserves special thanks for facilitating the final stages of data analyses through provision of computer facilities and the opportunity to return summers to KBS to teach Freshwater Algae.

Robert H. King's support and encouragement throughout the years are greatly appreciated as well as his technical assistance in the field every sunrise and sunset included in the study period. Thank-you Bob for being you.

Invaluable assistance in computer programming and data output were provided by Steven Weiss, John Gorentz and George Spengler.

Virginia Holt, Roger Ovink, Ken Wiest and LaRaine Wank provided technical assistance at various stages of the study; Arthur Wiest constructed the chambers and Gail Guth did the chamber and site cross sectional drawings. Charlotte Seeley and Alice Gillespie prepared the final manuscript and made the final stages of thesis preparation "enjoyable".

I would also like to thank Karen Dacey, Patricia Gage, Gordon Godshalk, Carolyn Hammarskjold, Virginia Holt, Mary Hughes, Marilyn Jacobs, David Mahan, Rosanna Mattingly, Marjorie Robbins, Steven Robbins, Charlotte Seeley, Mary Shaw, George Spengler, Jay Sonnad, Mary Lynn Teague, Dolores Teller and Arthur Wiest for their individual contributions, encouragement and friendship during the research and/or writing phases of this study.

The financial support for this study was provided by a Department of Energy Grant DE-AT06-79EV1004 for which I am thankful.

INTRODUCTION

As the sun proceeds slowly northward warming and lighting
the temperate streams, a golden glow results on rocks,
stones, and logs, announcing another diatomaceous spring...
20 March 1974 Augusta Creek

Interest in primary production of autotrophic organisms ranges from world wide support of the human population to unraveling the complex functions of ecosystems (MacFaden 1948, Wetzel 1975). Although there was early notice of primary producers and their importance in aquatic systems, it was not until 1944 that in-depth inquiries were begun. These early studies on lakes are summarized by Wetzel (1965, 1975a) and Lieth (1975). Early productivity studies on lotic systems are minimal (Odum 1956). Lotic systems are extremely heterogeneous and dynamic in all aspects. Besides the typical physical, chemical, spacial, and biological variables common in lentic systems, one studying lotic systems encounters variability in canopy cover, substrate distribution, and current; which in turn affect niche availability and distribution of organisms at all levels of food webs. These variables, along with watershed effects through runoff, flooding, and perturbations by man, are reviewed by Hynes (1970) and Whitton (1973), and their applicability to measurement of primary productivity discussed by Hynes (1970) and Wetzel (1975b). Methodology for estimating primary productivity in aquatic systems has been extensively reviewed (Ryther 1956b, Goldman, 1969, Vollenweider 1969,

Hall 1973, Hall and Moll 1975, Bott et al. 1982).

At the time of this investigation (1973 - 1975) no published in situ investigations had been made using chambers under natural field conditions in streams. Since this study, however, in situ measurements of community metabolism have been reported (Göthberg and Karlström 1975, Marker 1976b, Naiman 1976, Litke 1978, Pennak and Lavelle 1979, Sumner and Fisher 1979, Bush and Fisher 1981, Hornick et al. 1981), and a comparative study of three chamber techniques, including the chamber designed for this study (King chamber), and two open water techniques for estimating community metabolism has been completed (Bott et al. 1975). Although in situ chamber methods are beginning to take the forefront in the determination of community metabolism, Pennak and Lavelle (1979) and Rodgers et al. (1980) reinforce the lack of such data and the need to continue with this type of approach to examine ecological questions concerning community metabolism.

It was the purpose of this investigation to estimate in situ levels of community metabolism for selected riffle sections of the Augusta Creek watershed over a two-year period and to examine the autotrophic-heterotrophic relationships within these communities through measurement of autochthonous production and community respiration with subsequent calculation of the integrative parameters the ratio of gross community productivity to 24 hour community respiration ($P_G/R_{24} = P/R$) and net daily metabolism (NDM). First through third order (Strahler 1957) sites were examined to elucidate changes in community metabolism throughout the headwater portion of the watershed and the effects of light and temperature on the rates

of in situ productivity. Relationships of detrital and epilithon standing crops to community metabolism were also examined. The major hypotheses were that the shaded first order sections obtain minimal support through autotrophic pathways, which would indicate a heterotrophic dependence, while the open second and third order reaches would be supported by an autotrophic energy base over the annual period and that clearing of riparian vegetation from third order sections would increase the autotrophic potential of the riffle community.

Estimates of community metabolism have been shown to reflect environmental changes due to pollution (Odum 1956) or short term stress such as application of lampricides (Maki 1974). The P/R ratio and NDM are also of value in characterizing autotrophic-heterotrophic relationships in aquatic systems. Odum (1956), using P/R ratios from open water estimates, indicated the significance of this ratio in the classification of stream communities based on their major carbon source. He classified communities which received large amounts of allochthonous carbon in which respiration was greater than gross production ($P/R < 1$) as heterotrophic, while those in which there was much autochthonous production of carbon ($P/R > 1$) were termed autotrophic. This relationship has been established as a physiological classifier of streams by Caspers and Karke in 1966 and 1967 as reviewed by Pavletic et al. (1976). Hynes (1970) commented on the little attention that this valuable parameter had received in lotic systems. Fisher and Likens (1973) expanded on this relationship by incorporating estimates of export and import. Minshall (1978) reported $P/R < 1$ in aquatic plant-dominated lotic reaches, which

indicated the possibility of heterotrophic conditions in communities producing large amounts of autochthonous carbon. This carbon, however, is available to the community mainly when converted to detritus, often downstream, which indicates the heterotrophic nature of the riffle due to low attached algal development from shading by aquatic macrophytes. Estimates of NDM (gross community production minus 24 hour community respiration) yield a valuable quantitative measure of support or dependence of a community on allochthonous carbon sources (Bott et al. 1978, Vannote et al. 1980).

The heterotrophic nature of headwater streams and the importance of allochthonous inputs of organic carbon such as leaves, twigs, flower parts, bark, fine particulate organic matter (FPOM), and dissolved organic matter (DOM) is well documented as is the decomposition of these materials by bacteria, fungi, and macroinvertebrates within the deciduous biome (Minshall 1967; Kaushik and Hynes 1968, 1971; Triska 1970; Hynes 1970; Coffman et al. 1971; Cummins et al. 1973; Suberkropp and Klug 1974; Cummins 1974, 1975a, 1977, 1978, Suberkropp et al. 1976, Bell et al. 1978, Vannote et al. 1980). These studies indicate that heterotrophic stream sections receive as little as one percent of their carbon from autochthonous production.

Observations of forested areas of Augusta Creek, a woodland Michigan stream, indicated epilithic, epipsammic and epipellic algae were present, as well as high populations of algal-feeding aquatic insect larvae (scrapers; Merritt and Cummins 1978) such as Glossosoma and Neophylax (Trichoptera:caddisflies). Wetzel (1975b) and Minshall (1978) emphasized that in order to use an autotrophic-heterotrophic

classification system one must first know the magnitude of community production and not assume autotrophic insignificance. In situ measurements of community metabolism not only estimate productivity, but total community production, which includes both autotroph and heterotroph (bacterial, fungal, and invertebrate) metabolism (Wetzel 1975b, Bott et al. 1978, Pennak and Lavelle 1979). Such estimates are directly dependent on light, temperature, carbon dioxide, and oxygen levels and indirectly on inorganic and organic nutrient availability, which all affect photosynthesis and respiration (Lieth 1975; Wetzel 1975a, 1975b). Intensive investigation of the effects of these parameters on in situ community metabolism has not been completed. The extent to which autotrophic communities develop and contribute to the structure and function of woodland streams needs to be addressed.

DESCRIPTION OF STUDY SITE

The pussywillows have popped their bud scales and the Cornus with a blushing glow awakes from it's dull red winter slumber! They now await the stirring of leaf buds... Spring is in the air at Augusta Creek.

5 March 1974

Augusta Creek, a woodland stream located in Barry and Kalamazoo counties, Michigan, was the site of this investigation (Figure 1). This third order (Strahler 1957) stream system joins the Kalamazoo River in Augusta, which in turn flows westerly into Lake Michigan at Saugatuck. The watershed has been described by Mahan and Cummins (1974) as having a total length of 73.3 km (39.3 mi) and a drainage area of 72.3 km^{-2} (27.9 mi^{-2}). The watershed includes a combination

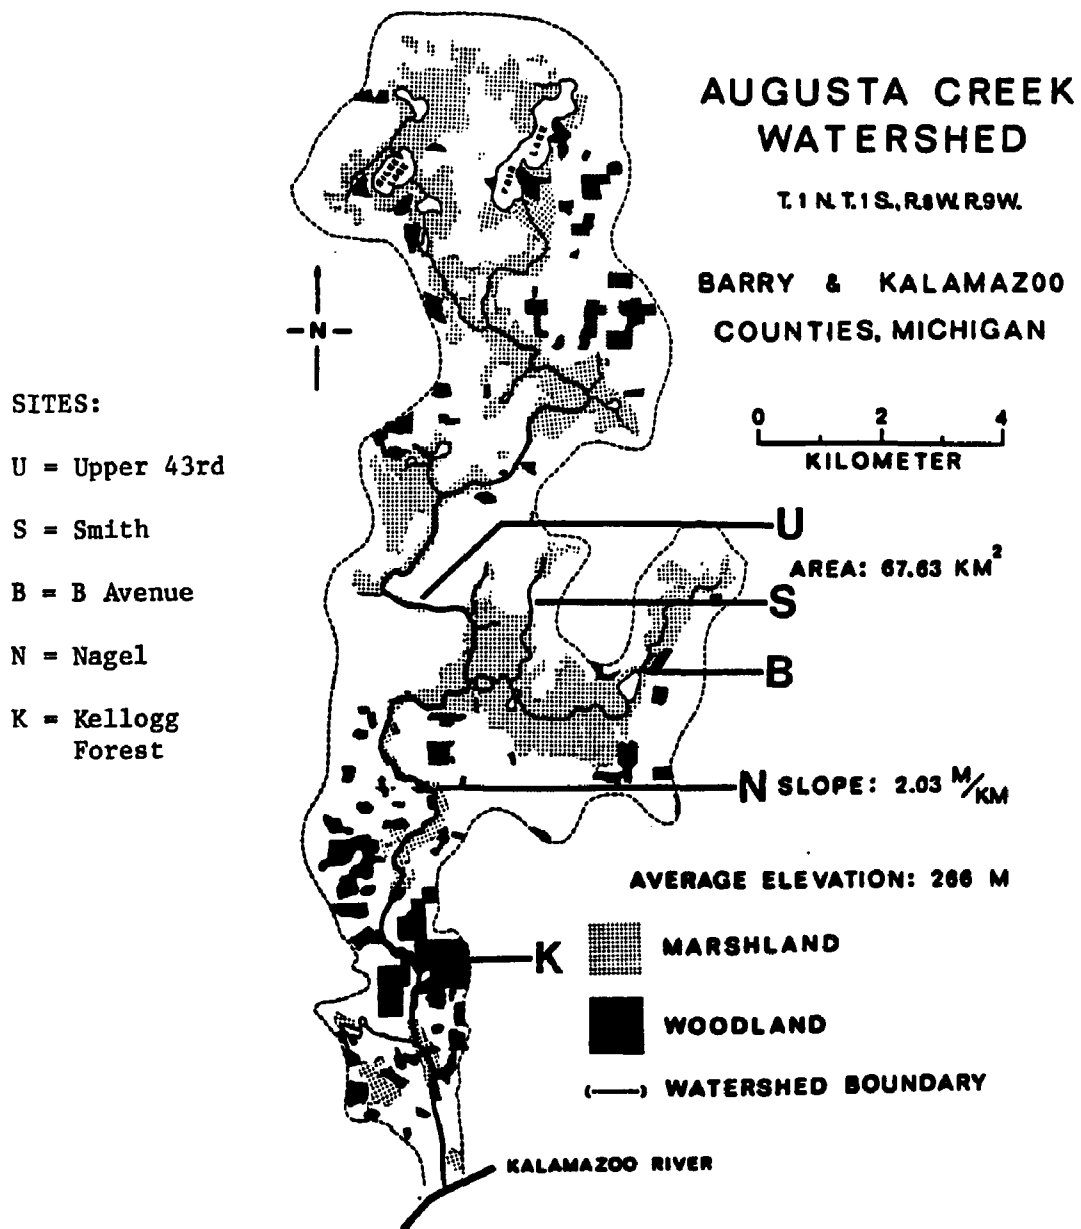

Figure 1. Augusta Creek watershed, Barry and Kalamazoo counties, Michigan (modified from Manny and Wetzel 1973).

of forested, meadow, and agricultural reaches with approximately 50% of the drainage in agricultural use (King 1979, Mahan 1980). The slope is slight, $2.03 \text{ m}^{-1}\text{km}^{-1}$ (Manny and Wetzel 1973), and discharge measured at the United States Geological Survey gauging station in Augusta (Figure 2) ranged from $8.72 \text{ m}^{-3}\text{s}^{-1}$ (308 cfs) in 1975 to $0.27 \text{ m}^{-3}\text{s}^{-1}$ (9.5 cfs) in 1970 and averaged $1.19 \text{ m}^{-3}\text{s}^{-1}$ (42 cfs) (Mahan and Cummins 1974). King (1978) gives weekly velocities and discharge values for the B Avenue, Nagel and Kellogg Forest Sites from 1973 to 1974 and discharge records from 1976 to 1977 at these sites plus Smith and Upper 43rd Sites are cited in Mahan (1980). The range and average discharge values for the sites selected for this investigation are summarized in Table 1.

Augusta Creek is characterized as a hardwater stream with pH values of 7.5 to 8.7, alkalinity of $160 \text{ to } 230 \text{ mg}^{-1}\text{l}^{-1}$, and total hardness of approximately $280 \text{ mg}^{-1}\text{l}^{-1} \text{ CaCO}_3$ (Manny and Wetzel 1973, Mahan and Cummins 1974, King 1978). Inorganic nitrogen levels ranged from $2 \text{ to } 5 \text{ mg}^{-1}\text{l}^{-1}$ and orthophosphate from $10 \text{ to } 40 \text{ }\mu\text{g}^{-1}\text{l}^{-1}$ during a diel study by Manny and Wetzel (1973).

The present investigation concentrated on riffle sections of two sites in Augusta Creek (B Avenue and Nagel) during 1973-1974, while riffles of five sites (Smith, B Avenue, Upper 43rd, Nagel, and Kellogg Forest) were studied in 1974-1975 (Figures 1 and 2). The Smith Site typifies a natural first order site within the Augusta Creek watershed and joins the B Avenue tributary before confluence with the Upper 43rd reach (Figures 1, 2, 3). The B Avenue first order reach originates in a tamarac (Larix laricina) area, flows southwest through an agriculturally perturbed section where cattle have free access to

Figure 3. Woody vegetation profiles of Smith and B Avenue sites, Kalamazoo County, Michigan (1975).

the stream, then flows into Hamilton Lake (Figures 1, 2, 3). The second order Upper 43rd meadow reach is within the tributary started by Gilkey and Fair Lakes and is downstream from Lawrence Lake (Figure 1); it joins the B Avenue - Smith tributary to form a third order system. The third order Nagel Site, located near the center of the drainage is an open reach influenced by swimming, fishing and vegetation removal (Figures 1, 2, 4). Along the east bank riparian vegetation was present, but in places the west bank was a mowed lawn (Figure 4). The Kellogg Forest Site is owned and maintained in a "natural" forested condition by Michigan State University and is open to the public for fishing. It is located downstream from the cleared Nagel site and provided a comparison of forested and cleared third order reaches.

Percent cover, as well as the major woody canopy components, determined from transects (30 m x 1 m) established perpendicular to the stream banks are illustrated in Figures 3 and 4. The narrow Smith and B Avenue reaches were heavily shaded and contrast with the open meadow reaches of Upper 43rd and Nagel Sites. The Kellogg Forest Site, was a shaded third order reach along Augusta Creek. An extensive analysis of the woody vegetation for these five sites was made by Mahan (1980). Of the 41 taxa observed in the herbaceous understory of the transects only five had abundant (> 50% occurrence) or common (> 10% occurrence) status (July 1974). Sedges (Carex spp.) were common or abundant at all sites except B Avenue, Grasses (Graminae) were common at Nagel Site, skunk cabbage (Symplocarpus foetidus (L.) Nutt.) was common at B Avenue, goldenrods (Solidago spp.) at Upper 43rd site, and forget-me-knots (Myosotis sp.) were

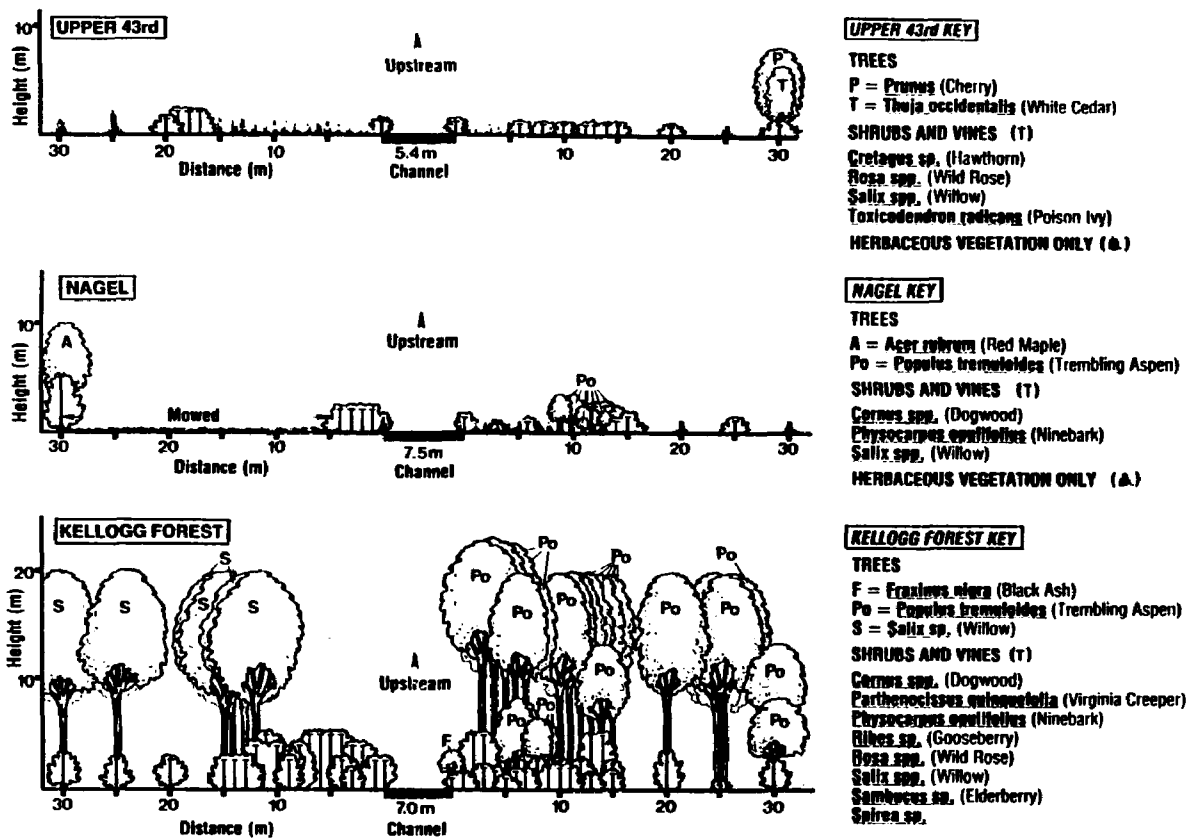

Figure 4. Woody vegetation profiles of Upper 43rd, Nagel, and Kellogg Forest sites, Augusta Creek, Kalamazoo County, Michigan (1975).

common at the Kellogg Forest (Table 2). At Upper 43rd and Nagel Sites emergent vegetation was present as well, including Peltandra virginica (L.) Kunth. and Sagittaria latifolia Willd. During the summer at the Nagel Site, much of the riffle was covered by submergent S. latifolia, Sparganium, Potamogeton pectinatus L., and P. nodosis Poir.

The physical composition of the sediments for the five sites, after Cummins (1962), was determined by particle-sizing into the following categories: pebbles (> 16 mm), gravel (> 4 mm), very coarse sand (> 1 mm), medium sand (> 250 μ m), and very fine sands (> 75 μ m). All sites were dominated by the larger particle-sizes with 65 to 81 percent composition of 16 and 4 mm substrates (Figure 5). The Smith and B Avenue Sites were very similar and on the lower end of the average (65 and 66% respectively), while the Upper 43rd (76%), Nagel (81%) and Kellogg Forest (77%) Sites were similar and had a higher proportion of particles greater than 16 mm in diameter. Travertine deposits were noticeable on the rocks at Upper 43rd, and Nagel, which reflected increases in photosynthetic activity and the alkaline nature of the water; travertine was absent at Smith and B Avenue, and intermediate in development at Kellogg Forest.

The macroinvertebrates, which accounted for greater than 10% of the standing crop over an annual period, included 19 taxa: five mayflies (Ephemeroptera), five caddisflies (Trichoptera), one riffle beetle (Coleoptera), six dipterans with a predominance of midges (Diptera), the amphipod Gammarus, and a water mite (Hydracina) (Table 3). The B Avenue Site had the highest number of common taxa (13), although the overall diversity was highest in the open reaches (Table 3).

METHODS

Indeed the spring diatom bloom is such a pleasant snake free period on Augusta Creek... 5 March 1974

Estimates of community metabolism were measured over a two year period (1973-1975) in five selected riffle sections of Augusta Creek, Michigan, using an in situ chamber technique (Figure 2). Circular chambers, illustrated in Figure 6, were constructed of 3.2 mm (1/8") thickness Plexiglas cylinders of telescoping diameters. The bottoms were 21.5 cm in diameter by five cm deep, while the lids were 22 cm in diameter by approximately 10.2 cm in height. A hole was cut in the lids for the insertion of a stopper in which a YSI (Yellow Springs Instrument Co.) self-stirring oxygen probe (Model 5420-A) was mounted. All bottoms and dark lids were opaqued with Krylon flat black paint and covered with two layers of black electricians tape applied in opposite directions to prevent light penetration (APHA et al. 1971). Chambers were 0.036 m^{-2} in area, held approximately 1500 ml of sediment and three liters of water.

Chamber bottoms were filled with natural substrate and buried in riffle sections of Augusta Creek (Figures 1 and 2) where they were allowed to recolonize at least one month prior to experimentation.

Just prior to an experiment YSI oxygen meters (Model 51-A temperature compensating) and oxygen probes were calibrated with oxygen probes in 100% humidity chambers which were submersed in the stream and equilibrated to stream temperature. Water samples were taken with a VanDorn water sampler and fixed in the field for Winkler titration of dissolved oxygen (APHA et al. 1971) at the beginning and

Figure 6. Plexiglas chamber designed for estimating community metabolism in stream riffle sections.

end of each experiment to check probe calibration. An average deviation of $\pm 0.5 \text{ mg O}_2 \text{ l}^{-1}$ ($n = 38$) was found from Winkler results for initial oxygens, while $\pm 0.04 \text{ mg O}_2 \text{ l}^{-1}$ was the average deviation of final titrations ($n = 38$). The precision of the YSI probe system was $\pm 0.2 \text{ mg O}_2 \text{ l}^{-1}$ (Yellow Springs Instrument Co.). Checks on probe drift and oxygen consumption of empty chambers were run at room temperature in the laboratory and in temperature controlled experimental stream channels with no significant changes observed ($\pm 0.2 \text{ mg O}_2 \text{ l}^{-1}$).

A complete field procedure diagram is illustrated in Figure 7. At the start of an experiment, Plexiglas viewers were used to locate chamber bottoms in the substrate. Markers were not used so the bottoms would remain inconspicuous in the sediments. The first two or three bottoms located in the predawn light were selected as replicates, provided they were not washed out. This method of selection was considered random.

Plexiglas lids were placed over each chamber and due to the closeness of fit, plus layers of electrician's tape, a tight seal was obtained (chambers could be lifted out and set on the stream bank with no water loss). Half-hour changes in oxygen and temperature were monitored using polarographic oxygen sensors equipped with electric stirrers. The stirrer provided a current within the chamber to better simulate stream conditions. Although the flow was not laminar, it was sufficient to thoroughly mix the water within the chamber, as evidenced by the almost instantaneous dispersal of test dyes or observations of attached detritus and algae that indicated swaying to be similar to that outside of the chamber. Laboratory and field

Figure 7. Experimental design of in situ community metabolism field experiments.

FIELD PROCEDURE

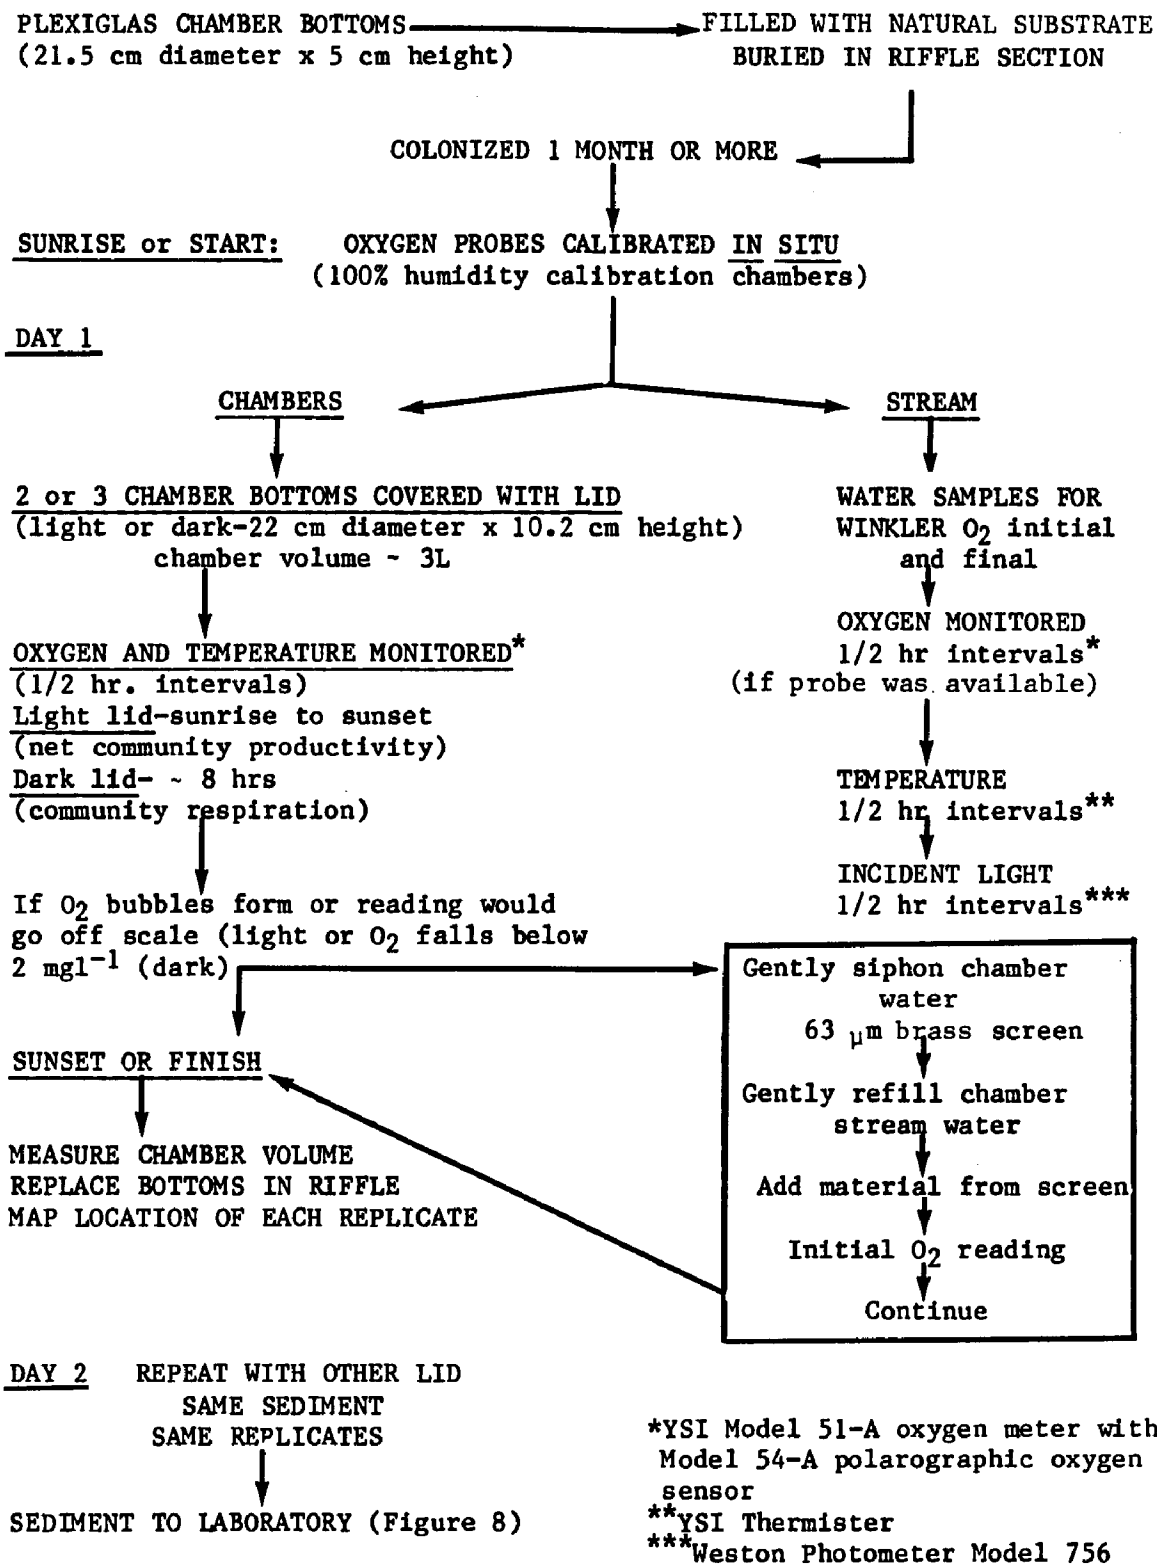

Figure 7.

studies have indicated currents of less than 15 to 2 cm s⁻¹ affect CR and mineral uptake in lotic systems (Odum and Hoskin 1957; Whitford and Schumacher 1961, 1964; Pfeifer and McDiffett 1975). The oxygen-probe stirrer is designed to create a current of at least 10 cm s⁻¹ over the membrane (YSI Instrument Co.). Estimates of community metabolism obtained with these chambers compared favorably (within expected variation for the reach) with those in which laminar flow was provided (Bott et al. 1978). The stirrer was run in the field using 12 volt car batteries and a Wards Power Verter (Model 2V200B).

Each experiment consisted of a two day sampling period. One day a light lid was placed over each replicate chamber to monitor net community productivity (NCP) from sunrise to sunset and the second day to monitor community respiration (CR) on the same substrate dark lids were employed (days were always consecutive). Dark runs were for variable lengths of time (generally daylength), but continued until an oxygen change of at least 2 mg l⁻¹ occurred, which placed measurement error at 10% (\pm 0.2 mg l⁻¹). Dark runs followed by diel light runs were completed at the B Avenue and Nagel sites to compare CR rates obtained during daylight and dark periods. There were no measurable differences in the two rates, therefore daylight monitoring of CR continued (Table 4).

Stream temperatures and levels of incident light were also monitored at half-hour intervals, using a YSI Thermister or a mercury thermometer and a Weston Photometer (Model 756), respectively.

At experiment termination the chamber volumes were measured and the sediments taken back to the laboratory for removal of detrital content through decanting, and sorting of macroinvertebrates (Figure

7). During the second year of sampling, the organic content of attached periphyton assemblages, and POM and algae incorporated in the travertine, was determined by ashing and reported as epilithon (g AFDW m^{-2} ; Figure 8). All POM was oven dried at 52 C to a constant weight (48 hours or greater). Ash free dry weight (AFDW) was obtained by ashing at 550 C for 24 hours (Figure 8). When epilithon AFDW was determined, detritus was gently elutriated from the inorganic sediments; then materials were collected separately, particle sized and AFDW determined for both components.

Macroinvertebrates were removed from either entire chamber sediments or subsamples (40 ml of 500 ml) of a sediment slurry (Figure 8). Using Chi-Square analysis for random distribution of organisms, it was determined that subsampling was adequate ($P < 0.05$) to estimate this component (Elliott 1971). Macroinvertebrates were dried (52 C) and AFDW determined as for sediments.

Duplicate estimates of community metabolism were completed on a monthly basis at the B Avenue site from January 1973 through May 1974 and at the Nagel site from August 1973 to August 1974. Seasonal estimates were made at five sites (Smith, B Avenue, Upper 43rd, Nagel and Kellogg Forest) from October 1974 through July 1975). Seasons were delineated as follows: Fall - September through November, Winter - December through February, Spring - March through May, and Summer - June through August.

Parameters calculated are listed and defined in Table 5 (Hewlett-Packard 2100A Mini Computer). Regression analyses, involving individual estimates of NCP and CR and averages of the parameters listed in Table 5 with the independent variables light, temperature

and AFDW, were completed (Biomedical Computer Programs P-Series (BMDP); Health Sciences Computing Facility, UCLA, NIH Special Research Resources Grant RR-3; Vax-11/780 digital computer, Kellogg Biological Station).

The contribution of the epilithon as well as the detrital flora of various sediment sizes to the NCP and CR during February - March, June and August at these five Augusta Creek sites (Figure 2), was determined using two Gilson Differential Respirometers (Model 20; Gilson 1963, Lawton and Richards 1970). Triplicate samples, picked macroinvertebrate free, of detritus and inorganic sediment particle-sized in 4 mm, 1 mm, 250 μm , 75 μm , and 0.45 μm categories, were run at the ambient stream temperatures under 15,000 lux (GE Power Groove bulbs) for estimates of NCP and in darkness for estimates of CR (Figure 9).

Samples were allowed to equilibrate under the lights for one hour prior to 15 minute estimates over a three hour period. The respirometers were then darkened for an equilibration period (1 hour), and a subsequent three hour dark estimates. All vessel contents were filtered on pre-weighed 0.45 μm Millipore filters, dried at 52 C, weighed, and ashed at 550 C for 24 hours for determination of AFDW (Figure 9). Estimates of NCP and CR were expressed as $\mu\text{l O}_2 \text{ g AFDW}^{-1}$ and $\text{g O}_2 \text{ m}^{-2}\text{d}^{-1}$ (G. L. Spengler modification of Petersen's 1974 respiration program; Hewlett-Packard 2100 A Mini Computer at the Kellogg Biological Station Computer Facility).

RESULTS AND DISCUSSION

Sunlight reflecting off Augusta Creek is jubilant in
early spring wherein lies a diatomaceous carpet...
March 1974

Physical Parameters

The range and average stream temperatures and incident light based on half-hour interval measurements at each site during the experimental runs, were used to characterize the conditions of metabolic estimates (Appendix D, Tables D 1-5).

Temperature

Based on weekly maximum-minimum temperature data from Augusta Creek sites (1973-1977; King 1978, Mahan 1980) temperature patterns were similar throughout the drainage with maxima ranging from 24.6 C at B Avenue to 29.6 C at Upper 43rd (Table 1). During this study similar trends were evident with maxima ranging from 19.9 C at B Avenue and Smith Sites to 24.8 C at Upper 43rd Site with Nagel and Kellogg Forest Sites attaining maxima of 23.9 and 22.2 C respectively (Appendix D).

Average daily temperatures exhibited typical temperate region seasonal trends at all sites (Figure 10). Mean daily temperatures ranged from 0.4 C at the Upper 43rd Site in January to 22.6 C at the Nagel Site in August. Maximum daily averages at the other sites were: Smith 17.6 C, B Avenue 17.6 C, Upper 43rd 21.7 C, and Kellogg Forest 19 C. Although large differences in temperatures were not evident, the first order Smith and B Avenue Sites had the lowest temperatures, the open Upper 43rd (second order) and Nagel (third order) the

Figure 10. Average daily temperature values for selected sites in the Augusta Creek watershed, Kalamazoo County, Michigan (1973-1975).

highest, while those of the downstream forested third order Kellogg Forest Site were intermediate (Figure 10, Appendix D).

The greatest daily temperature fluctuations occurred in the first order sections during spring and summer (10.5 C) and were similar to fluctuations reported for an Arizona desert stream by Bush and Fisher (1981). However the greatest average daily fluctuations were at the Upper 43rd Site (4.0 C) followed by the Nagel Site (3.4 C) and indicated the influence of lack of canopy (Table 6). The lower Nagel average emphasized the presence of cold springs and perhaps increased volume at a third order reach (King 1978), while the stability of the Kellogg Forest temperatures probably represented increased discharge and shade effects. Since the metabolism experiments were run on a consecutive day basis such daily fluctuations were important. Consecutive day differences were significantly less than daily differences in range and average and varied from 27 to 50% of the average daily temperature fluctuations (Table 6).

Light (Irradiance)

Light (= irradiance) patterns at the five sites followed expected temperate region seasonal and site trends (Figures 11 and 12). Shading was indicated at the Smith, B Avenue, and Kellogg Forest Sites with maximum levels at the Upper 43rd and Nagel sites (Figures 11, 12; Table 7). The highest average daily light levels were recorded in May at the Upper 43rd Site (90,213 lux), and the Nagel Site (84,631 lux) and the lowest level was 2,391 lux during January at the B Avenue Site. The highest light levels were recorded at all sites during April, May and June, reflecting the approach of the summer solstice.

* Seasonal data only

** Maximum

Leaf emergence at the shaded sites significantly decreased light levels in June, while abscission increased light in October when incident light is on a gradual decline in the temperate latitudes (Figures 11 and 12). Lower light values at Smith and B Avenue, even during periods when leaves were not present, indicated the shading effect by tree "skeletons".

The annual patterns of average daily lux indicated positive relationships with stream cover and width. Narrow first order reaches had minimum light, wider unforested reaches had maximum and the 7.0 m shaded Kellogg Forest reach intermediate levels (Figures 3, 4; Table 7). Autotrophic zones, according to the continuum concept, generally will be limited in natural stream reaches of 10 m or less in width (Vannote et al. 1980). Because of canopy alteration at the second order Upper 43rd and third order Nagel Sites, significant light inputs resulted. As well, significant levels occurred at the forested Kellogg Forest Site (66% of the open sites; Table 7).

The percentage of maximum daily light (Upper 43rd) received by each site ranged from 25 to 85% at the Smith and Nagel sites, respectively (Table 7). If the Kellogg Forest is considered a typical shaded third order reach the first order sites received 42 to 46% of maximum light in contrast to 28 to 30% of the open site (Table 7). The difference in light at the two open sites may be accounted for by the orientation of the channel (Upper 43rd E-W and Nagel N-S), as shown by Kobayasi (1961) for a canyon stream; variability in days monitored; or the increased observations at the Nagel Site (n = 8 Upper 43rd, n = 30 Nagel).

The complexity of the light regime at the shaded Kellogg Forest

Site, represented in Figure 13, illustrated the predictable variation in potential autotrophic zones during leaf-out of riparian vegetation and reflected the heterogeneity with which one must contend in estimating in situ metabolic activity, hopefully, viewed as a challenge rather than a deterrent to in situ measurements.

Community Metabolism

The interrelationships of autotrophic and heterotrophic components within lotic communities has been of interest for some time. Only recently, concomitant with this investigation and the advent of field chamber techniques, have estimates of community metabolism been made on discrete communities (Bombowna 1972, Pfeifer and McDiffett 1975, Marker 1976b, Bott et al. 1978, Pennak and Lavelle 1979, Sumner and Fisher 1979, Bush and Fisher 1981, Hornick et al. 1981). Such studies allow analyses of the producing or consuming modes of the community and thus, the autotrophic-heterotrophic balance within. Community metabolism studies have followed the approach for studying lotic systems outlined by Shelford and Eddy (1929) with several excellent artificial stream and laboratory chamber studies completed prior to in situ work (Whitford and Schumacher 1961, 1964; Edwards and Rolley 1965; Kevern and Ball 1965; McIntire and Phinney 1965; McIntire 1966; Maki 1974; Pfeifer and McDiffett 1975).

Methods and standardization of data presentation for studies of community metabolism are still in a state of flux. Many methods have been presented, however, often no mention is made of what was measured (i.e. gross versus net community productivity); standardization of units (oxygen, carbon, calories, gram calories, chlorophyll (various

Figure 13. Daily light patterns at Kellogg Forest, Augusta Creek, Kalamazoo County, Michigan on 25 July 1975.

pigments or total), glucose, dry weight, AFDW); or how the results are expressed (m^{-2} , m^{-3} , mg^{-1} chlorophyll, g^{-1} dry weight, g^{-1} AFDW, per chamber, etc.). Various estimates of PQ (photosynthetic quotient) and RQ (respiratory quotient) also complicate the situation of converting oxygen values to carbon and based on the few studies completed on periphyton communities, these quotients appear to be highly variable (PQ 1.45 to 2.6, RQ 0.85 to 1.1; Schindler et al. 1973, Bott et al 1978, Bott and Ritter 1981). Oxygen and ^{14}C estimates of community metabolism have been shown to measure similar magnitudes of productivity in coral reef communities (Littler 1973) and littoral zones of freshwater lakes (Hunding and Hargrave 1973); yet Schindler et al. (1973) compared four methods (oxygen, dissolved inorganic carbon, ^{14}C uptake and disappearance) and found little agreement other than general trends. They attributed the discrepancies to inappropriate PQ and RQ values for the gaseous methods. Bott and Ritter (1981) compared ^{14}C and oxygen estimates of community productivity in riffle communities and reported similar patterns of productivity, but lower estimates were obtained using the ^{14}C method; PQ values varied, which reinforced the necessity of measuring PQ, as values were generally higher than previously reported.

Since the conversion of oxygen uptake to carbon fixation is not reliable, data from this investigation will be presented, as measured, as oxygen and compared with those studies reported in oxygen units. (Table 8). This study, based on intact riffle communities and not isolated substrates, should yield a more realistic estimate of in situ metabolism of riffle reaches in Augusta Creek.

Gross Community Productivity

GCP, the most cited parameter in the productivity literature, indicates the maximum carbon producing capacity of the autotrophic community and is estimated by the addition of NCP plus CR for the photo-period. Much of the GCP may in turn be respired by the autotrophs. Verduin (1956) noted that the autotrophic community respired up to 80% of the GPP in phytoplankton studies while Hargrave (1969) and Hunding (1971) reported 13 to 15% of GCP respired by periphytic algae. In the present study NCP and CR were obtained from the same sediment on consecutive days, therefore it was assumed that similar heterotroph respiration rates were involved in both NCP and CR estimates.

Intrasite seasonal and intersite variations in GCP occurred annually at riffle sites of Augusta Creek (Figure 14). The lowest GCP values were recorded for the first order sections (Smith 0.09 to 0.18 g O₂ m⁻²d⁻¹ and B Avenue 0.01 to 0.59 g O₂ m⁻²d⁻¹), the open Nagel and Upper 43rd were highest (0.53 to 5.35 and 0.34 to 3.25 g O₂ m⁻²d⁻¹ respectively), and the shaded third order Kellogg Forest reach was intermediate (0.53 to 2.16 g O₂ m⁻²d⁻¹; Figure 14; Appendices A, B). On an annual average basis they ranked from lowest to highest: Smith, B Avenue, Kellogg Forest, Upper 43rd, and Nagel (Table 9).

Odum (1956) stated that streams may well be among the most productive environments on earth. However, his statement was based on standing crop estimates and ecosystem studies, using the upstream-downstream oxygen method for estimating productivity, in streams often enriched by organic pollution. Literature GCP values using the

upstream-downstream method (Odum 1956) range from $0.51 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ in a natural second order creek of the prairie biome in Kansas (Gelroth and Marzolf 1978) to $48.0 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ in Blue River Oklahoma (Duffer and Dorris 1966; Table 8). Chamber and light-dark bottle estimates ranged from $0.09 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ on revetments of the Danube River (Ertl and Tomajka 1973) to $12.5 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ in Cladophora mats of Sycamore Creek, Arizona (Bush and Fisher 1981). Chamber techniques have been developed to monitor rates of community metabolism in environments with low productivity and in riffle sections where more sensitive methods are essential. The rates of GCP from riffle communities in Augusta Creek ranged from 0.09 to $0.59 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at the shaded Smith Site to the open Nagel Site, respectively. These rates are in the lower range of those reported for lotic communities (Table 8). Annual rates at the Smith and B Avenue sites are the lowest in situ measurements reported to date (Table 9; Appendix A). The Augusta Creek GCP maxima are similar to GPP rates of phytoplankton communities while the range is equivalent to terrestrial levels of GPP reported for deserts to temperate deciduous forests (Wetzel 1975a).

The narrow, shaded Smith Site had the lowest seasonal GCP values (Figure 14; Table 9). Although, on a qualitative basis algae were never obvious at the Smith Site, maximum GCP rates were recorded in May prior to leaf emergence, which was during the period of visual diatom bloom in the rest of the watershed.

The B Avenue site also exhibited low levels of GCP on an annual basis, but averaged twice those at Smith Site (Figure 14; Table 9). Maximum rates were measured in June, but within the range of variation rates were similar from April through October. Algal growth was never

obvious in the shaded reaches at B Avenue, but microscopic examination revealed a diverse array of pennate diatoms during the summer months. Annual rates of GCP at this site were similar to those obtained by Nelson and Scott in a 60-m wide piedmont stream in Georgia (1962); they attributed their low values to the presence of high silt loads limiting light penetration (Table 8).

The differences in average daily light received by the two first order Augusta Creek study sites was probably insignificant, as both sites were heavily shaded (Figure 3). The averages for the June to October period were 9,055 lux (n=4) and 8,512 (n=15) at Smith and B Avenue, respectively. Estimates of light-saturated photosynthetic rates in periphyton communities range from 8,000 to 62,000 lux (Kobayasi 1961, McIntire et al. 1974, McIntire and Phinney 1965, Adams and Stone 1973, Lester et al. 1974). The averages for Smith and B Avenue Sites indicated potential shading effects with frequently less than light-saturated photoperiods (Appendix D). CR rates were similar at both sites; but, Smith had slightly higher CR rates (0.56 g O₂ m⁻²d⁻¹) compared to B Avenue (0.53 g O₂ m⁻²d⁻¹), therefore, higher estimates of GCP would tend to be at the Smith Site. Greater GCP at the B Avenue site was probably due to increased algal photosynthesis rather than an effect of CR rates.

The Upper 43rd and Nagel Sites were approximately 13 times more productive than the first order reaches (Figure 14). They also received much higher average light inputs (43,622 lux Upper 43rd and 36,959 lux Nagel) and exhibited a definite succession of attached algae. During the spring, diatom blooms, often nearly pure populations of Meridion circulare Agardh, carpeted all available

substrates. Diatoms were followed in late spring by patches of epipsammic Vaucheria, followed by a patchy summer distribution of Cladophora and blue-green mats dominated by Oscillatoria. A second pulse of diatoms, a mixed association of pennate forms, developed in autumn.

At Upper 43rd the rates of GCP increased in May, remained high throughout the summer and fall, and then decreased significantly during winter. Based on chamber estimates from larger order riffle communities (Table 8), the rates of GCP for Upper 43rd Site (0.34 to $3.25 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$) were higher than anticipated for a second order reach. By comparison, in a natural shaded second order section of Lost Creek, Kansas, Gelroth and Marzolf (1978) reported rates of 0.51 to $1.21 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$, while in a cleared and channelized section rates of GCP rose to $4.16 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$, similar to maxima for the Upper 43rd reach.

The third order Nagel Site followed the same seasonal trend as Upper 43rd, but maximum productivity was measured during August (Figure 14) and represented the highest GCP values recorded. These high Augusta Creek rates are similar to those reported by authors using the upstream-downstream technique in various systems (Table 8) and chamber techniques on an open third order stretch of White Clay Creek, Pennsylvania (Bott et al. 1978). The range of 0.66 to $5.35 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ obtained for Nagel Site was similar to the chamber GCP estimates of Marker (1976b), Litke (1978), and Sumner and Fisher (1979) (Table 8). Based on these comparisons, canopy removal at the Nagel Site shifted the position of this site in the theoretical continuum (Vannote et al. 1980) to reflect the primary productivity of

a naturally more open fourth order reach.

The shaded third order Kellogg Forest site averaged 47% the GCP of the cleared Nagel site ($1.3 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$). An increase in spring plateaued to summer values, then decreased during the fall and winter (Figure 14; Appendix A). The range of 0.53 to $2.16 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ over the annual period was within the range of studies cited in Table 8. Both maximum and minimum values were lower than those obtained at the cleared Nagel Site and from a naturally shaded fourth order Chippewa River, Michigan, riffle section (Litke 1978). Average light at the Kellogg Forest Site was 66% that of the open reaches (Table 7) with patchy algal development that was never as obvious as at the open Nagel Site. Similar differences in shaded versus unshaded reaches of the same order have been reported by Gelroth and Marzolf (1978), Gregory (1980), Hornick et al. (1981).

Maximum levels of GCP occurred during May and June at Smith, B Avenue and Upper 43rd Sites, while the Kellogg Forest maximum was in July, and Nagel in August (Figure 14). Seasonal trends such as these are typical of aquatic systems of the temperate region (Teal 1957, Cushing 1967, Stockner 1968, Hargrave 1969a, Flemer 1970, Gargas 1970, Hunding 1971, Hall 1972, Vannote and Ball 1972, Helan et al. 1973, Schindler 1973, Profet and Ransom 1974, Marker 1976b, de laCruz and Post 1977, Gelroth and Marzolf 1978, Sumner and Fisher 1979, Hornick et al 1981). The lowest GCP occurred during the winter at all sites of Augusta Creek, a pattern also characteristic of studies in which GCP was monitored on an annual basis (Cushing 1967, Stockner 1968, Ertl and Tomajka 1973, Marker 1976b, Sumner and Fisher 1979).

Viewing natural streams as a continuum (Vannote et al. 1980), the

hypothetical Augusta Creek site ranking based on levels of GCP would proceed from headwater downstream (Smith, B Avenue, Upper 43rd, Nagel, Kellogg Forest). Based on increasing in situ estimates of GCP they were: Smith, B Avenue, Kellogg Forest, Upper 43rd, and Nagel (Table 9). The open Upper 43rd and Nagel Sites illustrated the effects of perturbation by man, while the more natural state of a third order reach was shown by the Kellogg Forest results. The occurrence of open areas increases the complexity of community metabolism patterns in temperate woodland stream riffle sections. Natural and man-produced open areas are typical of present day stream systems and must be considered in applying the continuum concept. Such discontinuities in the continuum are treated in the intermediate disturbance hypothesis of Ward and Stanford (1981).

Net Community Productivity

Net community productivity (NCP), defined as the rate of carbon reduction minus usage in community respiration during the photoperiod, can be measured directly as oxygen gain or loss using the oxygen change technique. Radioactive carbon tracer uptake experiments (^{14}C) approximate NCP rates (Vollenweider 1969, APHA et al 1971, Schindler et al. 1973, Hunding and Hargrave 1973, Matheke and Horner 1974, Bott and Ritter 1981). NCP is of interest from an ecological standpoint since it represents the carbon available for use, storage, or export within a community. Likens (1975) points out that this is the commodity of interest to consumers and would therefore be important in community and ecosystem modeling. Pratt and Burkson (1959) stated that carbon produced in excess of metabolic need is equivalent to that

quantity that can be exported without change in community standing crop. The majority of work on primary productivity in lotic systems has been orientated towards quantitative or distributional studies (GCP) or laboratory experiments examining effects of physical parameters on rates of primary productivity. Few estimates of NCP exist in the literature (Grzenda et al. 1968, Stockner 1968, Hunding 1971, Adams and Stone 1973, Littler 1973, Cadee and Hegeman 1974, Bott et al. 1978, Bott and Ritter 1981) and not all of these cited are from lotic systems.

Estimates of NCP at the five Augusta Creek sites ranged from a maximum of $4.02 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at the Nagel Site in August to a low of $-0.25 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at the Smith Site in October (Figure 15; Appendices A, B). Ranked in increasing order of average NCP $\text{m}^{-2}\text{d}^{-1}$ the sites were in the same order as for GCP (Table 9; Figure 14).

Although photosynthesis was taking place at the first order sites, as indicated by the positive annual GCP values, the NCP was zero or less with the strongest negative trend at the Smith Site (Figures 14, 15; Table 9). Dependence of headwater streams on detrital input from the watershed with primary production often responsible for less than one percent of the annual carbon budget has been shown by Minshall (1967), Kaushik and Hynes (1968), Coffman et al. (1971), Fisher and Likens (1973), Sedell et al. (1975), and Bell et al. (1978). The low rates of NCP coupled with the higher detrital standing crops found at the Augusta Creek first order sites indicated a dependence on allochthonous carbon (Table 9). As discussed for GCP, average light inputs on an annual basis and especially during periods of leaf-out, were undoubtedly limiting the autotrophic potential at

Figure 15. Average rates (\pm SE) of NCP at selected riffle sites in the Augusta Creek watershed, Kalamazoo County, Michigan (1973-1975).

these sites (Table 7; Appendix D).

In addition to light limitation, grazing may also have accounted for the lowered levels of NCP at Smith and B Avenue Sites. Hargrave (1969a, 1972) reported low production in the littoral sediments of Lake Marion and Lake Esrom which he attributed to grazing. Kesler (1981), documenting significant grazing effects on attached algae, reported grazing pressures by the midge Corynoneura scutellata to account for 3 to 70% of the NCP. Populations of the scraper caddisfly Glossosoma nigor were abundant at the B Avenue site, and occurred at lesser densities at all other locations, therefore, one might speculate that they were influential in reducing the standing crop of algae and NCP.

The open Upper 43rd and Nagel sites had the highest autotrophic potential of the Augusta Creek sites studied with no significant difference in NCP evident between sites (Figure 15; Table 9). Summer rates measured at Upper 43rd and Nagel sites were similar to those reported by Bott et al. (1978) for an open third order reach of White Clay Creek, Pennsylvania.

NCP at the Kellogg Forest Site was significantly lower than the Nagel reach, but similar to Upper 43rd in average NCP (Table 9). The major divergence was notable during the summer leaf-out period (Figure 15). During this period the average light at the Kellogg Forest was 3,493 lux d⁻¹, similar to January levels at this site (Appendix D), and well below light saturation levels of periphyton communities (8,000 to 62,000 lux).

It has been estimated that in aquatic communities 15 to 80% of the GCP may be respired by the in place community (Verduin 1956,

Hargrave 1969a, Hunding 1971), which leaves a net gain of 20 to 85% as NCP. The average NCP as a percent of average GCP for Augusta Creek sites was highly variable: -128.5% Smith, -7.6% B Avenue, 57% Upper 43rd, 60% Nagel, 69% Kellogg Forest. The shaded first order sites with negative average deficits are unique to the primary productivity literature, while the open sites (Upper 43rd and Nagel) and shaded third order (Kellogg Forest) site, averaging 62% NCP, were similar to the estimated range in the literature. This again illustrates the dependence on allochthonous carbon sources and the heterotrophic nature of shaded first order Augusta Creek sites and obvious shifts in the magnitude of NCP due to clearing illustrated by the comparison of the Nagel and Kellogg Forest Sites.

Community Respiration

Community respiration (CR) is the rate of oxidation of organic matter to inorganic carbon dioxide by the autotrophic and aerobic heterotrophic components combined. In this study CR was measured on intact riffle communities including the smaller particle-sizes of sediment and detritus versus selected stream substrates placed in chambers. Intact in situ community simulation must be kept in mind when comparing CR rates of this study with other studies, because inclusion of all particle-sizes may increase CR estimates, since small particles may be heavily colonized by bacteria and to some extent fungi and algae (Suberkropp and Klug 1974, Madsen 1975). However, rates may also be lower due to lack of community disturbance and less exposure of surfaces to higher oxygen levels.

No attempt was made in the present study to partition CR.

Hargrave (1969a) attributed 33% of CR to macroinvertebrates, 45% to bacteria, and 15% to algae and Edwards and Rolley (1965) estimated 40% respired by macroinvertebrates in soft sediments. Both of these studies were from lentic communities. On a biomass basis, the macroinvertebrates were a small percentage of the total organic content of the Augusta Creek substrates and therefore might be expected to account for less than the estimated 40 to 45%.

With early interest in the effects of pollution on oxygen uptake, estimates of CR have been made in lotic systems since the 1930's (i.e. Butcher et al. 1930, Calvert 1933). Since Odum's (1956) introduction of the upstream-downstream procedure for estimating community metabolism in streams, many estimates of CR have appeared in the literature, but few in situ chamber estimates have been made (Table 8).

Rates of CR ranged from 0.24 to 3.67 g O₂ m⁻²d⁻¹ during January at the B Avenue Site and July at the Nagel Site, respectively (Appendices A, B; Figure 16). The annual averages (g O₂ m⁻²d⁻¹) for each site ranked in increasing order were: B Avenue 0.52, Smith 0.56, Kellogg Forest 0.75, Upper 43rd 1.79, and Nagel 1.88; this pattern was similar to that of ranked sites for GCP and NCP (Table 9).

Smith and B Avenue CR values were very similar, with the lowest rates observed in the winter, followed by significant increases in spring, stable summer values, and decreasing rates from late fall to low winter values (Figure 16). The Smith Site had an autumn maximum in CR during leaf-input, but was only based on four observations. Further, a more comprehensive data set from B Avenue did not show such a maximum (Figure 16). Autumnal peaks in CR have been reported and

Figure 16. Rates of average CR (\pm SE) for selected riffle communities in the Augusta Creek watershed, Kalamazoo County, Michigan (1973-1975).

related to increased detrital inputs in various other systems (Teal 1957, Nelson and Scott 1962, Flemer 1970, Hargrave 1972, Maki 1974).

Significantly higher rates of CR were observed at the Upper 43rd and Nagel sites than the first order reaches (Table 9). Based on four observations, the Upper 43rd Site had lowest CR during the winter, but steadily increased to a July maximum and remained high through the fall (Figure 16). Although the Nagel Site illustrated a more erratic pattern, maximum and minimum rates occurred during the same periods as at Upper 43rd. The highest CR for all sites was observed during July at the Nagel site (Appendices A, B; Figure 16), which was also during the period of maximum light, day-length, temperature and Cladophora development (Appendix D). Rates at both the Nagel and Upper 43rd Sites declined in August, possibly due to the decline of the green and blue-green community. Other studies noting summer maxima include Butcher et al. (1930), Stockner (1968), Flemer (1970) Vannote and Ball (1972), de laCruz and Post (1977), and Sumner and Fisher (1979).

The average CR at the Kellogg Forest was intermediate among the sites (Table 9), but most similar to the rates at Smith and B Avenue sites. Only during the summer were CR values for the three sites significantly different (Figure 16; Table 9). Summer increases at the Kellogg Forest were attributed to increased light availability during this period (Appendix D, Figures 11, 12). The similarity between the Kellogg Forest third order reach and the first order sections is the relationship predicted by the continuum concept (Vannote et al. 1980).

In the open reaches increases in CR as well as primary productivity were observed with rates of average CR ($1.8 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ Upper 43rd, $1.9 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ Nagel) similar to the open third order

White Clay Creek, Pennsylvania (Bott et al. 1978; Tables 8, 9). CR values obtained for riffle communities of Augusta Creek were generally in the low range of upstream-downstream studies reported in the literature and within the ranges reported for chamber estimates (Table 8). Thus, patterns of CR observed in Augusta Creek were not unusual, but reinforced, by in situ measurements, the general magnitude of respiratory activity in natural and perturbed reaches of first through third order riffle sections of temperate streams and specifically illustrated the effects of riparian zone clearing.

Community respiration, ranked as a percentage of GCP (annual average) for Augusta Creek sites was: Smith 445%, B Avenue 200%, Upper 43rd 82%, Nage 60%, and Kellogg Forest 55%. Literature values of CR/GCP as a percent typically range from 13 to 68% (Kobayasi 1961, Pamatmat 1968, Hunding 1971, Gallagher and Daiber 1973); Likens (1975) 0 to 95%. The first order sites did not fit within the latter range, apparently due to low NCP. Such an analysis further indicates the dependency of these first order reaches on allochthonous carbon inputs. A definite and inverse relationship, especially at higher temperatures, was seen between NCP and CR at these two first order sites, and to a lesser extent at Upper 43rd Site.

P/R Ratio

The ratio of GCP to CR (P/R) over 24 hour periods is a valuable integrator of community metabolism, which allows comparisons and rankings of communities. As Humphrey (1975) noted, Ryther (1954) and Steele (1965) proposed P/R ratios as the main measure of community physiological state and, therefore, useful in studying marine and

lentic freshwater systems. Odum, comparing the magnitude of in-stream photosynthetic production (autotrophy) to the import of organic matter from the landscape (heterotrophy) as energy sources, first applied P/R ratios in flowing water systems. The use of this parameter in stream classification was further reinforced by Hynes (1970) and Pieczynska (1970). Fisher and Likens (1973) proposed that the P/R ratio should be used in conjunction with the import/export ratio in characterizing a stream reach. Vannote et al. (1980) stated that estimates of P/R allow characterization of the biological processes of a stream reach as to the productive (autotrophic) or consumptive (heterotrophic) mode, thus the present community usage of various inputs is indicated. However, caution must be exercised; if the P/R ratio is <1 , the source of carbon (i.e. imported, or stored from earlier autochthonous production) cannot be delineated from the P/R alone. Pavetić et al. (1976) suggested monitoring P/R in running waters in the spring, when light and dark periods are equal, to characterize a reach physiologically, but unfortunately their usage of P_G/CR might caused confusion with the conventional terminology (P_G/CR 24).

Each Augusta Creek site displayed a constant pattern in P/R (Figure 17). The ratios measured at the Smith and B Avenue sites were consistently below one, but above one at Upper 43rd, Nagel and Kellogg Forest. (Figure 17; Appendices A, B). Such consistency has been reported by other lotic investigators (Stockner 1968, Cole 1973, Sumner and Fisher 1979) and by Ganning and Wulff (1970) in brackish rock pools. Others such as Flemer (1970), Vannote and Ball (1972), Hall (1972), and Bott et al. (1978) reported fluctuations in P/R from greater than to less than one in stream reaches and Mathis et al.

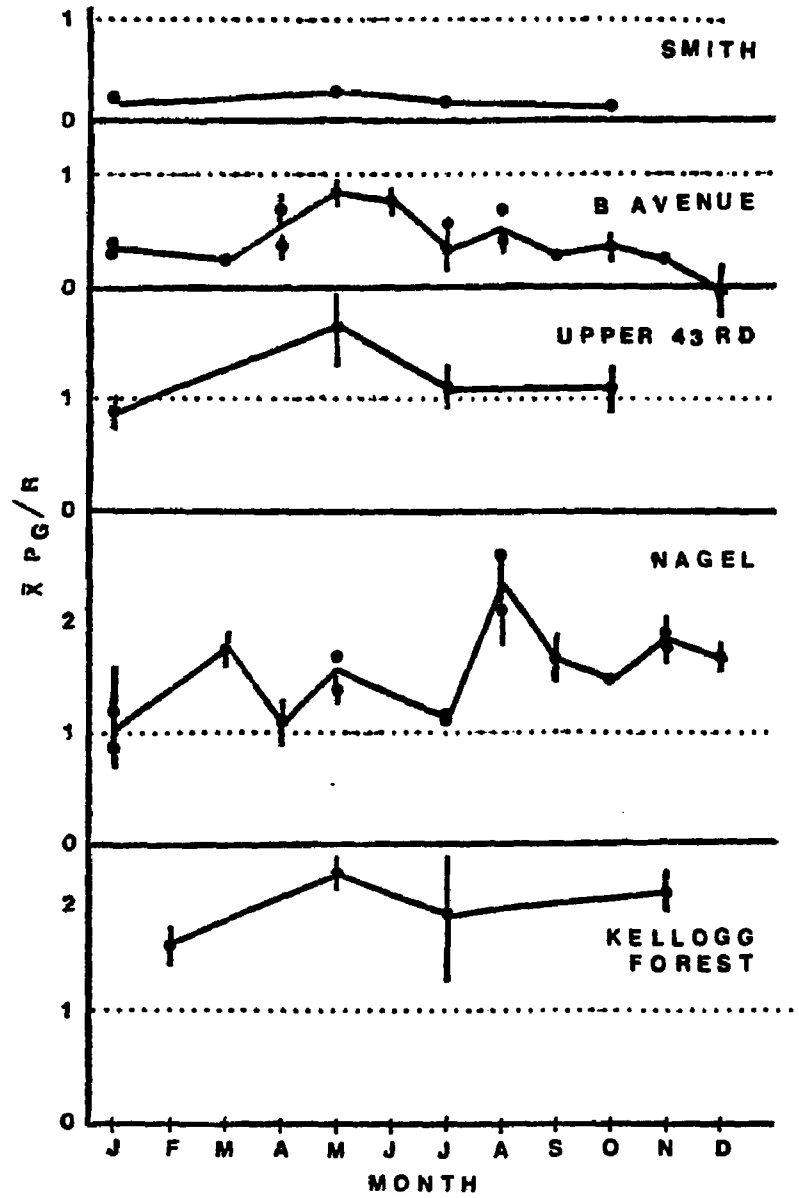

Figure 17. Average P/R ratios (+ SE) for selected sites in the Augusta Creek watershed, Kalamazoo County, Michigan (1973-1975).

(1969), investigating a flood plain lake, found P/R greater than one except during turbid periods caused by winds or flooding. It is feasible that those communities, such as the Upper 43rd Site which have stabilized near a $P/R = 1$, would be more likely to fluctuate above and below one, while distinctly heterotrophic or autotrophic communities would remain as such, unless altered by man.

Based on a comparison of the average P/R ratios at the two sites monitored on a monthly basis for a year with the next years seasonal data for these sites (B Avenue and Nagel), seasonal estimates adequately reflected the autotrophic-heterotrophic nature of the sites (Table 10). The average P/R ratios at all sites ranged from 0.21 at the Smith Site to 1.97 at Kellogg Forest (Table 9; Appendix A). Monthly daily estimates ranged from -0.02 in December at B Avenue to 2.5 during August at Nagel Site (Table 9; Figure 17). Sites ranked by average from lowest to highest were: Smith 0.21, B Avenue 0.45, Upper 43rd 1.2, Nagel 1.57, Kellogg Forest 1.97. This trend corresponds with the continuum hypothesis of increasing autotrophic support as one proceeds from headwaters to sixth order streams (Vannote et al. 1980). P/R ratios compared to leaf processing in Augusta Creek at these sites indicated an inverse relationship between P/R ratio and litter processing (Cummins 1980), and indicates a decreased effect of CPOM from first to third order reaches.

Although the Kellogg Forest Site had lower average GCP than the Upper 43rd and Nagel Sites, the CR was significantly lower (within the confidence limits of Smith and B Avenue Sites) accounting for the increased ratios. Comparing the detrital and epilithon standing crops of Nagel, Upper 43rd and Kellogg Forest the depressed CR at this

Table 10. Annual and seasonal estimates of P/R ratio at two sites of Augusta Creek, Kalamazoo County, Michigan (1973-1975).

| Site | Period | \bar{X} P _G /R | S.E. | C.V. % |
|----------|----------------|-----------------------------|------|--------|
| B Avenue | Annual* | 0.42 | 0.07 | 60.1 |
| B Avenue | Seasonal** | 0.52 | 0.10 | 36.6 |
| B Avenue | Combined Years | 0.45 | 0.06 | 53.1 |
| Nagel | Annual | 1.65 | 0.14 | 27.4 |
| Nagel | Seasonal | 1.36 | 0.23 | 42.0 |
| Nagel | Combined Years | 1.57 | 0.12 | 29.1 |

* Annual (1973-1974)

** Seasonal (1974-1975)

site was probably due to a lesser development of epilithon since the detrital crops were not dissimilar (Appendix C). This relationship was confirmed by visual and qualitative microscopic examination of the algae. The P/R ratios greater than one indicated the importance of algal development and autochthonous production in naturally shaded sections of third order riffle reaches.

The Smith Site, with P/R ratios ranging from 0.19 to 0.29, indicated a consistent lack of primary productivity and therefore a dependence on allochthonous carbon sources. The heterotrophic nature of this site was further documented by the high detrital standing crop throughout the year, low levels of GCP, and negative values of NCP (Appendix C; Table 9). A very slight peak in P/R was noted during May, corresponding to the "highest" period of GCP (Figures 14, 17; Table 9). NCP was always a negative value at Smith as reflected in the low P/R ratios (Table 9, Figures 15, 17). Using the upstream-downstream method, low ratios of P/R have been reported for various stream reaches, especially turbid and polluted systems (Table 8). Chamber estimates of P/R from first order sections are lacking in the literature, and Smith values were lower than most reported values (Table 8).

The B Avenue riffle P/R ratios fluctuated over the annual period from -0.02, the lowest recorded at any site for the entire study (snowy overcast day), to 0.88 (Figure 17, Appendices A, B). These values excepting the lowest values, are within the range reported in the literature (Table 8). The maximum was during the spring when light was increasing and before leaf emergence, and corresponded with the highest GCP levels and the single positive value of NCP (Figures

14, 15, 17). Thus, the first order B Avenue site, based on consistently low P/R ratios, would also be classified as a heterotrophic reach with an annual consuming mode (Figure 17, Appendices A, B).

The second order Upper 43rd Site, had P/R values that ranged from 0.19 to 1.68. This was the only site which obtained a dynamic equilibrium near $P/R = 1$. These P/R values indicated a self-supporting autochthonous riffle community, with little excess organic matter to export or store. The low values obtained in January (Figure 17), illustrated the possibility of a heterotrophic shift, possibly supported by import or slight storage resulting from the spring maximum. GCP and NCP were high at that time as was CR which remained high throughout the summer (Figures 14, 15, 16). This relationship was reflected in the increasing levels of epilithon at the Upper 43rd Site (Appendix C). P/R values from this meadow reach were in the range found for Cladophora mats in Sycamore Creek, Arizona (Bush and Fisher 1981), fourth and fifth order reaches of the Roritan River, New Jersey (Flemer 1970), and the summer values obtained for a third order reach of White Clay Creek, Pennsylvania (Bott et al. 1978). The openness of the Upper 43rd site enhanced autotrophic production above that reported by others studying naturally wooded second order streams (de laCruz and Post 1977, Gelroth and Marzolf 1978). Presumably the P/R ratio would be lower if measured within the wooded section downstream for the study site.

Consistently autotrophic would characterize the Nagel Site, where P/R ratios ranged from 0.86 during January to 2.59 during August (Figure 17; Appendices A, B). This site remained autotrophic,

although the riffle flora changed drastically from little visible algal growth during the winter, to a carpet of diatoms in spring, through Cladophora and blue-green mats developing in summer along with aquatic macrophytes of the genera Potamogeton and Saggitaria. The March peak coincided with the diatom bloom and the August maximum with maximum Cladophora and blue-green development (Figure 17). Both peaks were also illustrated in the NCP patterns (Figure 15). P/R ratios at the Nagel Site compared most closely with chamber estimates reported by Bush and Fisher (1981) for Cladophora mats during the summer and Litke's natural fourth order riffle section of the Chippewa River, Michigan, (1978); values were within the range of several studies cited in Table 8. Although a consistent autotrophic base was indicated, the P/R values were lower than those of the Kellogg Forest Site (Table 9; Figure 17).

The Kellogg Forest range in P/R was 1.61 during the winter to 2.33 during the spring (Figure 17; Appendices A, B). A more stable type of community development at this site compared to the Nagel Site, was indicated by less variation in P/R. These riffle P/R ratios were higher than generally predicted by the continuum hypothesis (Vannote et al. 1980), which proposed little autotrophic activity in forest covered stream communities less than 10 m in width. Only the higher P/R ratios from other studies approximated the Kellogg Forest Values (Table 8) and illustrate the effects of increased light even for short periods of time on the autotrophic potential of a shaded third order riffle community. Even if the effects of pool metabolism lowered the P/R ratios of the entire reach, it is apparent that the riffles were making a significant contribution to the ecosystem energy flux.

Based on P/R ratios obtained, Upper 43rd, Nagel and Kellogg Forest Sites were characterized as having an annual producing mode (autotrophic), while Smith and B Avenue were in a continuous consumptive mode (heterotrophic).

Net Daily Metabolism

NDM ($P_G - R_{24}$) is another integrative measurement which helps delineate the producing or consuming mode of a community. Little attention has been given this quantitative, ecologically important parameter in the literature (Bott et al. 1978). Although the P/R ratio indicates the autotrophic potential of a site, it does not indicate amounts of excess carbon available for storage or export or the magnitude of deficit within a community, which must be compensated for by storage or allochthonous inputs for continued stable community metabolism as does estimates of NDM.

NDM data for Augusta Creek sites mirrored the NCP and P/R curves for each site, but were lower in magnitude (Figures 15, 17, 18). Average NDM ($g\ O_2\ m^{-2}d^{-1}$) when ranked by sites differed from that of P/R (Smith -0.44, B Avenue -0.26, Upper 43rd 0.45, Kellogg Forest 0.60, and Nagel 1.01; Table 9). Ranking by NDM indicated that even though P/R ratios were higher at the Kellogg Forest, the cleared third order Nagel Site produced more carbon over the year and that although open, the Upper 43rd Site produced less excess carbon than the shaded third order Kellogg Forest riffle (Table 9). All average NDM values were within the range reported for White Clay Creek (third order) by Bott et al. (1978). NDM values ranged from $-0.72\ g\ O_2\ m^{-2}d^{-1}$ during the fall at Smith to $2.68\ g\ O_2\ m^{-2}d^{-1}$ at Nagel in

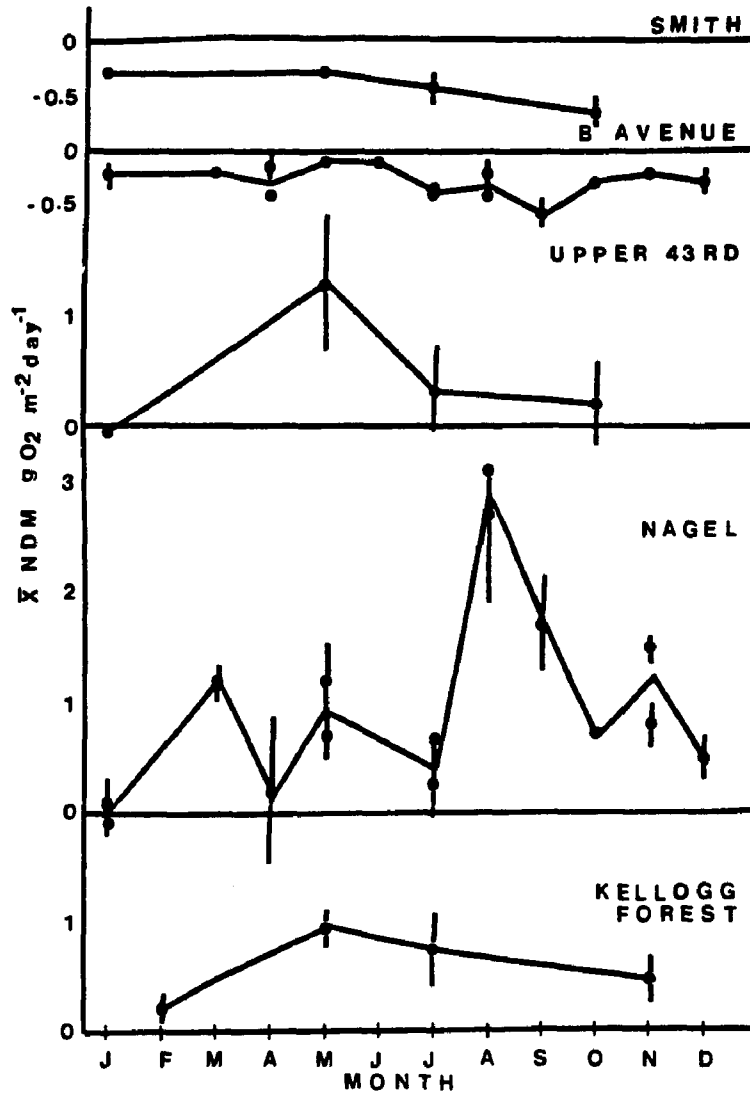

Figure 18. Average values (+ SE) of NDM for selected riffle sites in the Augusta Creek watershed, Kalamazoo County, Michigan (1973-1975).

August (Appendices A, B; Figure 18).

NDM at B Avenue and Smith sites indicated a dependence on allochthonous sources year around (Table 9; Figure 18). Upper 43rd was self-supporting through spring and summer with potential allochthonous dependence during the fall and winter. Given the magnitude of Upper 43rd spring NDM, stored autochthonous primary production could have supported this riffle (Figure 18). P/R ratios near one also support this hypothesis (Table 9). An increase in detrital standing crop during the fall, especially in the 1 mm and 250 μm particle sizes, with no corresponding decrease in epilithon, also indicated that inputs from upstream or the riparian zone occurred at this time (Appendix D; Figures 18, 19).

The Nagel Site, indicating a positive autotrophic capacity over the year, had the lowest NDM in January and the largest detrital standing crop at that time (Appendix C; Figure 18). Origin of this detrital increase is unknown, since export and import were not measured, but levels of NDM were adequate to support this riffle community on an annual basis (Figure 18; Appendices A, B). The low period in April, during the obvious spring bloom in attached algae, was the result of increased CR of the periphyton assemblage and was probably not supported by increased detrital standing crop (Figure 18). However, the July decrease correlated with decreased epilithon and an increase of small particle sizes of detritus, which indicates possible storage of autochthonously produced organic matter in the detrital pool (Appendix C; Figure 18). From the high NDM in the fall (Figure 18) and overall positive values of NDM it appears that the Nagel riffle section was self-supporting and autotrophic in nature.

Autochthonous organic matter supported the Kellogg Forest riffle section on a yearly basis (Figure 18; Table 9). The lowest values occurred during the winter, as at the other sites, when detritus was abundant and could have been of autochthonous or allochthonous origin. However, from the levels of NDM measured during the spring and summer, if stored as POM, autochthonous production could have supported this riffle community over the year (Appendix C, Figure 18). A stable pattern in NDM was observed at the Kellogg Forest Site with overlapping values at all seasons (Figure 18) and even though the P/R ratios were highest at this site (Figure 17), the NDM was lower than the open Nagel Site, which indicated a greater capacity in the open third order site to support riffle metabolism.

Detrital Standing Crop

The standing crop of detritus is an indication of the POM base upon which a heterotrophic community develops. Changes in standing crop may indicate shifts in the energy base (i. e. heterotrophic-autotrophic); changes in detrital and epilithon particle-size may help delineate origins of detritus or processing trends, and rates of metabolism can be expressed on a g^{-1} AFDW basis. As evidenced by SEM micrographs, both autotrophic and heterotrophic organisms colonize detritus (Suberkropp and Klug 1976). Visual observations of CPOM such as leaves indicated diatom colonization during the fall. Community metabolism of leaf packs colonized in Augusta Creek and monitored in chambers showed that during fall diatom blooms they may add to the total NCP of the ecosystem (King unpublished data).

Detrital standing crop estimates at the Augusta Creek sites

studied ranged from 592 g m^{-2} at the B Avenue Site during the fall (October) to 145 g m^{-2} at B Avenue in the spring (April; Figure 19). On an average basis Smith had the largest standing crop (388 g m^{-2}) followed by Nagel (291 g m^{-2}), B Avenue (290 g m^{-2}), Kellogg Forest (283 g m^{-2}), and Upper 43rd (240 g m^{-2} ; Table 9). As evaluated according to non-overlapping standard errors, values at Smith were significantly greater than all sites; B Avenue, Nagel and Kellogg Forest were essentially the same, while values at Upper 43rd were similar to those at Nagel and Kellogg Forest Sites (Table 9). Overall, these average values were quite similar, especially considering the measured differences in metabolic parameters (Table 9). Data collected from Augusta Creek by Cummins and Petersen (unpublished) and the River Continuum Group (Minshall et al. 1982) indicated similar annual averages and trends (Mahan 1980).

Maximum detrital standing crops occurred at three of the five sites during the fall (Figure 19). Upper 43rd and Kellogg Forest attained maxima in summer and spring, respectively. During the period of algal senescence, smaller particle sizes increased at Upper 43rd, which indicated potential storage of algal detritus (Figure 20). The spring detrital increase at the Kellogg Forest was not significantly different from winter and summer (Figure 19). Thus, the second and third order sites had more stable total standing crops than either of the first order sites.

The autumn input of CPOM was obvious at both Smith and B Avenue Sites (Figures 19, 20). At Smith there was a decrease in spring, probably reflecting the effects of scouring due to flooding. At B Avenue a rapid decrease in standing crop occurred during the autumn to

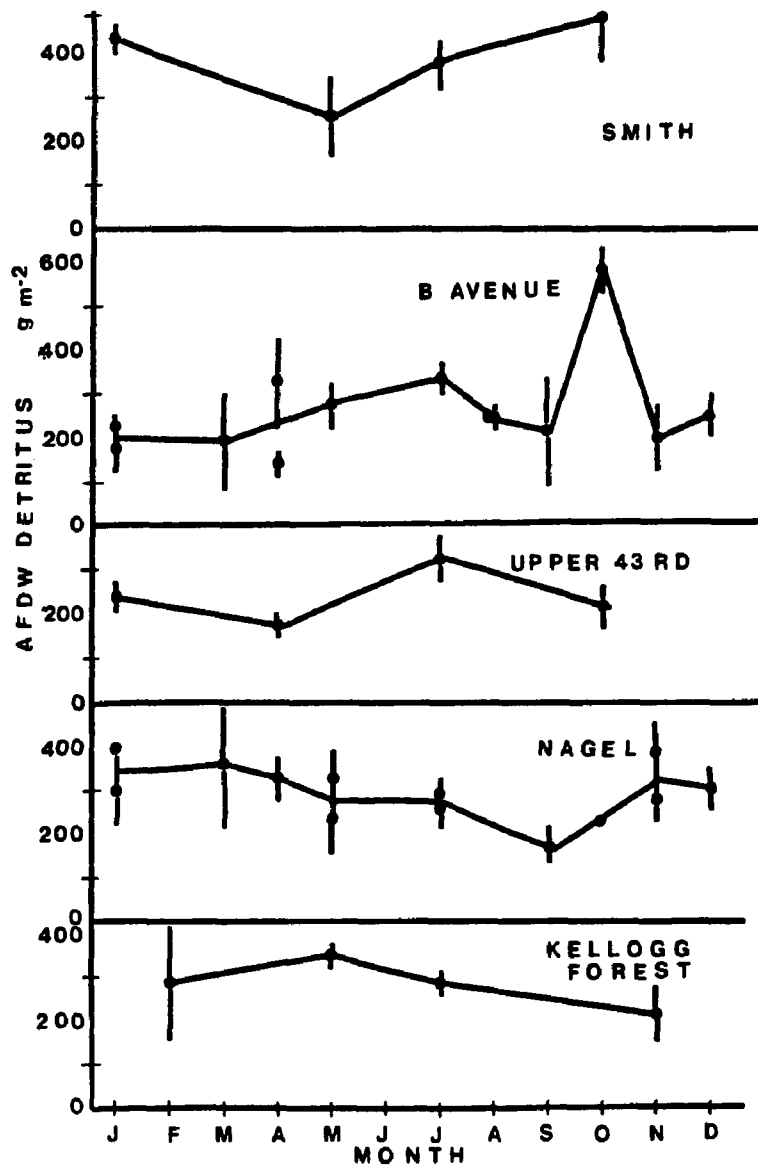

Figure 19. Average estimates of detrital standing crop (\pm SE) from selected riffle communities in Augusta Creek, Kalamazoo County, Michigan (1973-1975).

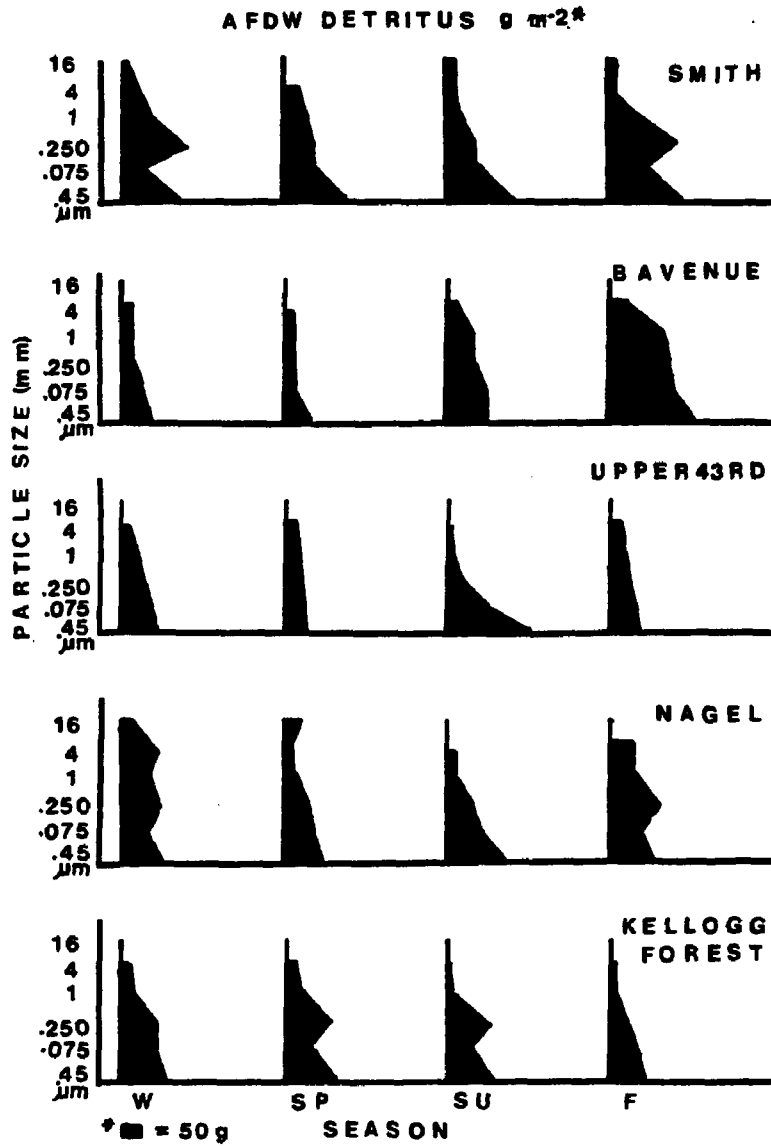

Figure 20. Seasonal distribution of particle-sized detritus from selected riffle sections of Augusta Creek, Kalamazoo County, Michigan (1973-1975).

low stable values winter and summer (Figure 19). Although variance was high these data suggested a spring input (Figure 19) of CPOM. Mahan (1980) found the highest CPOM inputs at Smith followed by Kellogg Forest, Upper 43rd (wooded section) and Nagel Sites. At all sites leaves were the dominant form of CPOM. The CPOM inputs in Smith Site were significantly higher during autumn and spring, with spring CPOM averaging 56% of the fall input. The quality, however, shifted from a dominance of leaves in fall to wood in spring. The other sites showed no marked fluctuation in inputs. The disturbed Nagel site was by far the lowest in CPOM inputs (Mahan 1980).

The consistency noted in second and third order tributary riffle sections in this study was also reported for a fourth order riffle of the Chippewa River, Michigan (Litke 1978). Such stability probably resulted from more continual autochthonous inputs mediating allochthonous inputs over an annual period. The stability of the community and carbon inputs were indicated by the P/R ratios and NDM of these sites (Figures 17, 18). Naiman and Sedell (1979b) suggested that this stability indicated a balance in processing, storage, export and import. If this is so, changes in P/R would serve as an indication of changes within the communities.

The relatively stable patterns observed for total detrital standing crop (Figure 19) are, however, not indicative of processing, changes in particle-size composition on a seasonal basis, or quality (i.e. labile-refractory nature) or turnover time of particles. Distribution of particle-size on a seasonal basis (Figure 20) illustrated changes occurred within the detrital pool. Although total detrital standing crop levels may be consistent at a site, shifts in

particle-size composition may illustrate dynamic changes within the riffles. All sites were dominated by FPOM with Smith Site having the highest annual average and Upper 43rd the lowest (Figure 20; Table 11). Greater fluctuations were found in the CPOM over the year than in the FPOM standing crop as indicated by the C.V.% (\bar{x} CPOM 50.6 and FPOM 30.8; Table 11). The most stable and also the lowest CPOM standing crop was found at Upper 43rd, while the FPOM was most consistent at the Nagel site.

Shifts in particle size at Smith were not large, but by spring 16 and 4 mm particles were not observed and the 250 μ m size decreased, either by processing or export, which were not monitored in this study. A more marked pattern was seen at B Avenue where the large autumn standing crops were reduced annually, which indicated significant export. However, a study of retention of basswood (Tilia) leaves at this site indicated that CPOM traversed a mean distance of 10 to 30 m before entrainment, and therefore storage and processing would occur within the reach with possible export of finer particles (Cummins et al. 1981). The distribution of FPOM was similar during all seasons with the shifts occurring in the CPOM range where lowest levels occurred during the spring, possibly the result of flooding, since corresponding increases in FPOM did not occur (Figures 19, 20). Spring allochthonous CPOM inputs may have accounted for the observed higher summer values (Figure 20).

The Upper 43rd particle-size specific distribution was more constant than the first order sites with algal inputs probably occurring during the summer as indicated by increases in the FPOM pool (Figure 20). Litke (1978) observed an increase in the detrital pool

Table 11. CPOM and FPOM detrital standing crops and CPOM/FPOM ratios from selected sites in Augusta Creek, Kalamazoo County, Michigan (1974-1975).

due to Cladophora inputs in a fourth order riffle during the summers. Such an increase was also observed at the Nagel Site, where CPOM levels were highest during the fall-winter period. The Kellogg Forest had little change in detrital particle-size distribution over the year, which indicated the influence of mainly non-filamentous autochthonous production at this site.

The CPOM/FPOM ratios ranged from 0.06 during the summer at Kellogg Forest to 0.68 in the winter at the Nagel Site. The lowest ratios, indicating the autochthonous energy base, were at the higher order sites during the summer and at B Avenue and Smith during the spring at the time of increased light and GCP "maxima". The highest ratios varied with site, but correlated with depressed P/R ratios (Figure 17; Table 11). The winter-early spring dependence on CPOM at the autotrophic sites correlated with low levels of GCP and NCP, while the autumn-winter inputs of CPOM and subsequent processing within the riffles coincided with the high CPOM/FPOM at the heterotrophic sites (Figures 14, 15; Table 11). Therefore, the P/R and CPOM/FPOM ratios can be used in conjunction to elucidate the autotrophic-heterotrophic relationships of stream riffles.

The annual average CPOM/FPOM ratios were highest in the shaded first order reaches (0.2 Smith and 0.34 B Avenue) and lower in the third order reach (0.12 Kellogg Forest). This pattern was in agreement with the continuum concept and reflected a greater dependence on autotrophic production as stream order increased (Vannote et al. 1980). However, the cleared Nagel section had the greatest average CPOM/FPOM ratio (0.4) and the highest average CPOM standing crop. When the S.E.'s are considered (Table 11), the Nagel

CPOM standing crop was comparable to those from Smith and B Avenue. Based on their overall productivity differences, the Nagel CPOM resulted from inputs of filamentous algae and aquatic macrophytes and thus, had been autochthonously produced as documented by Minshall (1978) in desert streams. Although the actual origins of allochthonous CPOM were not demonstrated, Mahan (1980) ranked Nagel the lowest in CPOM inputs of the four Augusta Creek sites studied, which supports the autotrophic input hypothesis. The meadow reach, Upper 43rd, average 0.23 CPOM/FPOM ratio, which was not significantly different from that at the Smith Site. Therefore, the generalization of decreasing CPOM/FPOM ratio with increasing order did not hold for open reaches of first through third order streams.

Detrital (AFDW) Community Metabolism

Little relationship between detrital AFDW and CR has been noted in the literature (Wetzel 1963, Edwards and Rolley 1965, Hargrave 1969b, Pennak and Lavelle 1979). Odum (1956) reported CR to be dependent on the concentrations of organic matter in the sediment, Edberg and Hofsten (1973) found the nature and quality of detritus had a decided effect on oxygen uptake in soft sediments, and Göthberg and Karlström (1975) found CR to be dependent on the amount of detritus present in riffle sections of the Ricklean River, Sweden. These findings contrasted to those of Hargrave (1969b) that organic content and composition appeared to have minor significance in oxygen consumption of littoral sediments. In a later study comparing mud, sand, and detritus in short term experiments Hargrave (1972) found detritus consumed three times more oxygen than sand, and that log

oxygen uptake was inversely related to organic content of sediment. Intuitively, CR would be linked most closely to detrital activity, and most studies have emphasized this relationship. Edberg and Hofsten (1973) indicated that CR of algal detritus was much higher than allochthonous forms, which may account for increases of CR during periods of algal growth and senescence. Detritus (especially CPOM) can also be a substrate for algal colonization and a relationship may exist between AFDW and productivity. Community metabolism estimates expressed on an AFDW basis may reflect changes in the composition of the detrital standing crop; increased productivity g^{-1} may indicate algal colonization of detrital particles or contribution to the detrital pool through sloughing from inorganic substrates, and increasing CR rates during spring or fall may indicate more labile algal contributions to the detrital pool.

Community metabolism expressed on a biomass basis (g^{-1} AFDW; Appendix A; Table 12) indicated the same trends (Figures 21, 22) as measured on an areal basis with the exception of CR (Figures 14, 15, 16, 18; Table 9). Smith and B Avenue were reversed in CR ranking by expression on a weight basis, but there was no significant difference between these values. Since the mean total standing crop estimates at all sites, excepting Smith, were so close one would not anticipate large changes in seasonal trends (Table 11). Periods of maximum and minimum values on an areal or biomass basis for these parameters (NCP, GCP, CR, NDM) were generally similar at all sites. Values at the Smith and B Avenue sites were most stable with only small annual changes. CR varied most of any parameter: summer and spring maximum rates occurred when expressed on an areal basis, while on a biomass

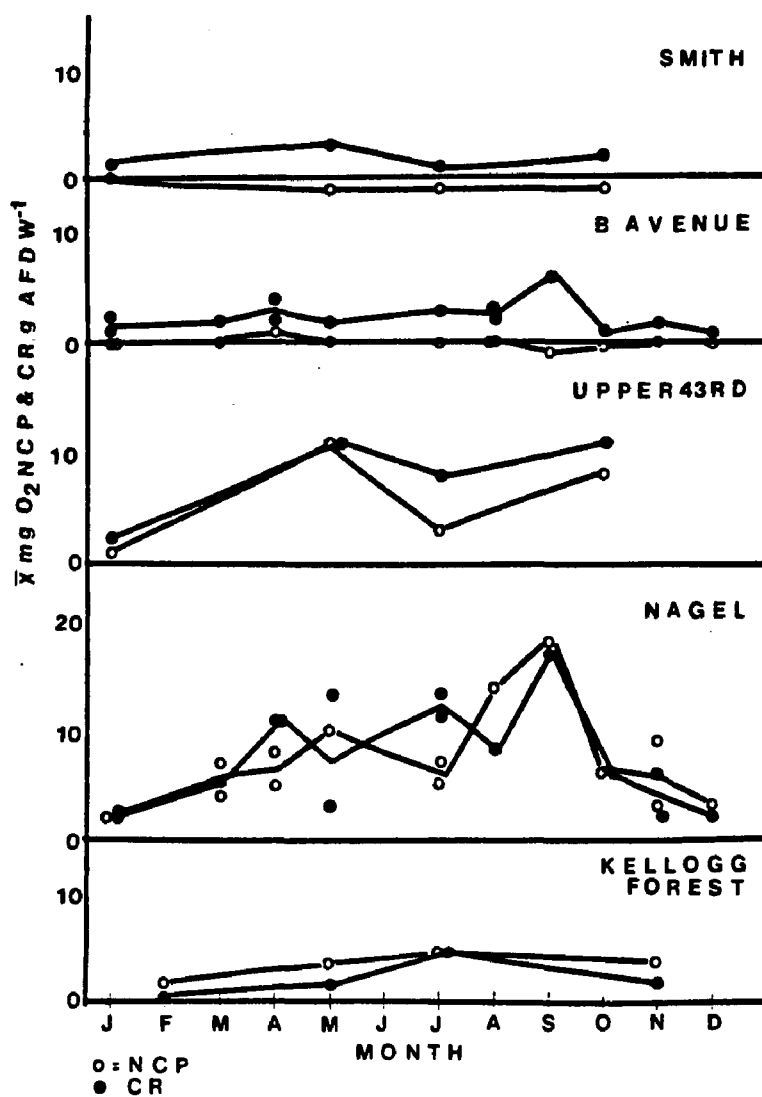

Figure 21. Estimates of NCP and CR on a weight basis from selected Augusta Creek riffle sections, Kalamazoo County, Michigan (1973-1975).

Figure 22. Estimates of GCP and NDM on a weight basis from selected Augusta Creek riffle sections, Kalamazoo County, Michigan (1973-1975).

basis the maximum was in the autumn (Appendix A; Figures 16, 21). At the Upper 43rd and Nagel Sites these increases in CR may have been the result of algal inputs to the detrital pool (Edberg and Hofsten 1973). Calow (1975) reported epilithic detritus was higher in organic matter and protein in comparison to adjacent detritus which was higher in lignin and cellulose. Thus, when periphyton assemblages slough into the detrital pool, higher rates of CR would be expected from the addition of a more labile substrate. It should be noted that in all cases values were low on a biomass basis and there was little difference in seasonal ranges (Table 12; Figures 21, 22).

The autotrophic Nagel Site had high levels of detrital standing crop and also had the highest values of most parameters on a biomass basis (Table 12). The high state of activity g^{-1} detritus at the Nagel site was also characteristic at Upper 43rd.

Based on average detrital standing crop, Smith was highest followed by Nagel, B Avenue, Kellogg Forest, and Upper 43rd. If metabolic parameters were directly correlated with total detritus the highest activity would have been at Smith Site, which had the lowest activity followed by B Avenue, Kellogg Forest, Upper 43rd and Nagel. Therefore, other factors such as light temperature or epilithon development and composition must be mediating metabolic activity.

Epilithon

Epilithon, is here defined as that organic assemblage of algae, bacteria, fungi, protozoans, detritus, and even small macroinvertebrates which colonize this mass, attached to inorganic substrates. This definition is often lumped with the category of

periphyton or Aufwuchs. Round (1965) has long campaigned to characterize the assemblage based on substrate colonized (i.e. epilithon - rocks and stones, epipsammon - sand, epipelon - mud, epiphyton - plants). The term epilithon has been used by Marker (1976a) to describe the biomass of benthic algae on rocks and Calow (1975) has studied epilithic detritus.

Epilithon biomass values (Appendix C) are based on the 550 AFDW of particle-sized inorganic substrates. Nelson and Scott (1962) ashed, rewetted and redried at 63C to attempt rehydration of clay particles. They estimated error due to loss of hydration at 5%. Losses of this type in Augusta Creek sediments to 75 μm in size would be small and no corrections were made. The method developed showed comparative differences between sites in Augusta Creek epilithon development.

Sediments throughout the Augusta Creek drainage were similar at all sites; they consisted of granite, basalt and limestone. However, visual differences of sediment surfaces were obvious between autotrophic and heterotrophic sites. Sediments from Nagel and Upper 43rd had obvious travertine deposits, Kellogg Forest intermediate in travertine build up, and Smith and B Avenue were free of visible carbonate deposits. In hardwater streams photosynthesis, shifting the equilibrium, can be responsible for deposition of CaCO_3 on sediments or aquatic macrophytes and subsequent travertine development (Hynes 1970, Wetzel 1975a). Photosynthetic activity was largely responsible for both visual and biomass differences between sites and epilithon development was a more reliable indicator of autotrophic-heterotrophic relationships of riffle sections than was detrital standing crop.

Sites ranked according to increasing annual average epilithon development were: Smith, B Avenue, Kellogg Forest, Nagel and Upper 43rd (Table 9; Figure 23). Using overlap of standard errors as a criterion, Nagel and Upper 43rd were essentially the same, Kellogg Forest intermediate, and Smith significantly lower than all other sites in epilithon development. These trends reflected the same pattern as NCP and GCP in Augusta Creek (Table 9).

Epilithon estimates ranged from 1480 g m^{-2} at Smith to 5038 g m^{-2} at Nagel Site during the spring. The maximum at the Nagel Site undoubtedly resulted from the diatom bloom which carpeted the substrate, while the low at Smith Site was attributed to spring scouring effects. These epilithon values from the alkaline Augusta Creek were higher than those obtained using the same method in soft water, turbid riffle sections of the Buttahatchie River Mississippi (Miller and King 1981). Their total AFDW estimates of sediments, characteristic of epilithon weights (Table 9), ranged from 260 to 363 g m^{-2} in August. Development of the autotrophic epilithon component in this system was limited by turbidity, thus, these levels characterize the contribution of the detrital component to the biomass. Epilithon values from six replicate chambers placed in a second order riffle of the west branch of the Clark's Fork of the Yellowstone River, Montana, where primary productivity levels were very low, ranged from 999 to 1892 g m^{-2} . The average (1338 g m^{-2}) was similar to that of the heterotrophic Smith Site of Augusta Creek (1763 g m^{-2}) as were the P/R ratios of approximately 0.3 (Table 9).

The first order detrital based systems of Augusta Creek ranged from 1480 to 2811 g m^{-2} epilithon. Both first order sites indicated

Figure 23. Estimates of eiplithon development, obtained on a seasonal basis from selected riffle sites of Augusta Creek, Kalamazoo County, Michigan (1974-1975).

less variance in epilithon estimates over the year with the C.V.% averaging only 18.3% at Smith and 16.6% at B Avenue in contrast to the overall average of 28.7% (Table 9). This consistency, indicating a balance within the riffle sections, was typical of most parameters at these sites.

The highest values of epilithon at Smith Site were during autumn (Figure 23) at the time of significant detrital inputs. The nature and consistency of epilithic detritus has been investigated by Madsen (1972). Using SEM techniques, detritus was the major component, bacteria and fungi were prevalent, with few algae evident. This material may be a rich source of organic matter (protein) to consumer organisms (Calow 1975). Colonization of stones by heterotrophs thus leads to organic accumulation and further entrapment of detritus all of which would be a component of the epilithon as determined by ashing. These levels at Smith Site were significantly different from the autotrophic based sites (Figure 23; Table 9).

Helan et al. (1973) ashed inorganic substrates from mountain streams in Czechoslovakia and found highest amounts of epilithon in the upper reaches during April and June, similar to patterns observed at B Avenue, Augusta Creek (Figure 23). The Kellogg Forest Site, intermediate in epilithon development, had little change in quantity of epilithon, and was consistently higher in values than the first order sites (Table 9; Figure 23). The open sites illustrated more significant seasonal changes, with the Upper 43rd Site maximum attained during the autumn after the autotrophic build up from a spring low (Figure 23). The Nagel site exhibited spring and autumn increases (diatom blooms) much like that reported for the middle

sections by Helan et al. (1973). The lower summer values at Nagel (Figure 23) reflected shading effects of extensive aquatic macrophyte growth during mid to late summer.

On a particle-size specific basis (Figure 24), changes occurred mainly in the 16 and 4 mm size fractions. McConnell and Sigler (1959) found larger substrates (12 cm and greater) to have more chlorophyll a content than smaller sediments, with less than 6% of the chlorophyll a concentration in sediments smaller than 2.5 cm in diameter. In English streams Marker (1976a) found 85% of the algal biomass on substrates greater than 6 cm. This pattern of highest autotrophic colonization on larger substrates was consistent with that in Augusta Creek. Based on productivity levels and visual observations, this assemblage at the autotrophic sites was due to algal development.

Since the epilithon standing crops in Augusta Creek riffles were so high compared to the detrital standing crop, total organic weight of the sediments followed the trends of the epilithon community. Detritus averaged 12% of the total particulate organic matter (TPOM), with the percentages ranging from an average of 18% at Smith to 7.5% at Upper 43rd (Table 13). Detrital percentages indicated a greater importance of detritus at Smith and the autotrophic nature of the Upper 43rd and Nagel riffles. This relationship was consistent over the annual period at all sites, although the magnitude of epilithon and detritus estimates varied. The heterotrophic riffle of the west branch of the Clark's Fork of the Yellowstone River, Montana averaged 4.2% non-attached detritus, which indicated the importance of non-photosynthetic epilithon in this system.

Epilithon/detritus ratios (E/D) establish an index of the

| | % E | % D | % E | % D | % E | % D | % E | % D | % E | % D | range E/D | \bar{X} E/D |
| Smith | 79 | 21 | 85 | 5 | 82 | 18 | 82 | 18 | 82 | 18 | 3.7-4.8 | 4.5 |
| B Avenue | 92 | 8 | 94 | 5 | 89 | 11 | 79 | 21 | 89 | 11 | 3.46-16.5 | 7.9 |
| Upper 43rd | 91 | 9 | 91 | 9 | 92 | 8 | 96 | 4 | 93 | 8 | 10.2-15.0 | 14.8 |
| Nagel | 91 | 9 | 94 | 6 | 88 | 12 | 89 | 11 | 91 | 10 | 7.5-15.4 | 12.0 |
| Kellogg Forest | 90 | 10 | 82 | 18 | 92 | 8 | 94 | 6 | 90 | 11 | 4.6-15.8 | 9.5 |

relative importance of the two components within riffles. Based on seasonal data, the average E/D for Smith Site was 4.5, B Avenue 7.9, Upper 43rd 14.8, Nagel 12.0, and Kellogg Forest 9.5 (Table 13). The closer the ratio is to one ($E = D$), the higher the dependence of the riffle section on non-attached detritus versus an epilithon assemblage. Conversely, the larger the ratio, the greater the dependence on the epilithon organic assemblage. The Smith and B Avenue Sites were more dependent on non-attached detritus than the other reaches. Annual average E/D ratios from Augusta Creek sites followed the patterns of average NCP and GCP (Tables 9, 13), which indicated an algal dominance in the epilithon at the autotrophic sites. The summer data from the west branch of the Clark's Fork of the Yellowstone River, Montana averaged 23.6 E/D; this value, higher than the autotrophic Augusta Creek sites, indicated an epilithon based community, although detrital, since levels of NCP and P/R were low. Rocks from this riffle were slippery to the touch during the study period, but not high in algal content. Therefore, the magnitude of this ratio indicates the importance of epilithon versus non-attached detritus within a system, but not the autotrophic-heterotrophic balance within the assemblage.

Seasonal patterns of E/D ratio exhibited no constant pattern except at the Smith Site (Figure 25). The values of approximately five measured at the Smith Site were indicative of consistent dependence on non-attached detritus as an energy base (heterotrophic). The B Avenue Site, indicating a more complex pattern of E/D, was also low in E/D average, similar to Smith Site. A spring increase in epilithon development concomitant with the spring diatom bloom in

Figure 25. Epilithon/Detritus ratios over an annual period for selected riffle sites of Augusta Creek, Kalamazoo County, Michigan (1974-1975).

Augusta Creek was reflected by an increase in E/D (Figure 25) at the B Avenue Site. The P/R ratio and values of NCP increased at this time as well, which indicated the increase in E/D was of algal origin (Figures 15, 17, 25). The autotrophic sites had an inverse relationship between GCP, NCP, and/or P/R with the E/D ratio. Autotrophic sites remained productive, but as epilithon increased, rates of primary productivity decreased or remained stable at all three sites. This pattern follows the generally accepted trend of decreased rates of primary productivity with periphyton assemblage build-up caused by self-shading and competition for light, carbon dioxide, and nutrients (Goldman 1964, Hynes 1970, Wetzel 1975a).

When one observes riffles within the deciduous biome it is generally the inorganic sediments which predominate and are the major substrates available for colonization, not detritus. Although the scientific literature focuses on water percolation through leaf packs in riffles, a major source of POM might well be the epilithon in many stream riffles. Winterborn et al. (1981) indicated that in New Zealand streams the organic component from inorganic substrates was important to the support of macroinvertebrates and suggested attention be refocused on the organic layer of stones. Therefore, the E/D ratio used with the P/R ratio should be a useful relationship to monitor in ecological investigations involving stream structure and function.

Factors Affecting Rates of Community Metabolism

Although researchers engaged in monitoring community metabolism may disagree, Lieth (1975) stated that measurement of primary productivity is not in itself a sufficient goal, but should be used as

a tool for characterization and interpretation of communities and their relationships to the environment. One needs only to scan the periphyton primary productivity literature to note investigations of regulatory factors on rates of community metabolism and contributions of the autotrophs to community structure and function. Most work has been completed in marine and freshwater lentic systems and includes investigations relating physical and chemical parameters to community metabolism of benthic communities from tidal flats (Pamatmat 1968, Ganning and Wulff 1970, Gargas 1970, Gallagher and Daiber 1973, Littler 1973, Cadee and Hegeman 1974), freshwater littoral zones (Felföldy 1961, Wetzel 1963, Hargrave 1969a, Hunding 1971, Hunding and Hargrave 1973, Schindler et al. 1973), experimental systems (Odum and Hoskin 1957, Felföldy 1961, Whitford and Schumacher 1961, 1964, Beyers 1962, McIntire et al. 1964, McIntire and Phinney 1965, Kevers and Ball 1965, Lester et al. 1974, Edberg and Hofsten 1973, Pfeifer and McDiffett 1975) and in lotic systems (McConnell and Sigler 1959, Kobayasi 1961, Cushing 1967, Stockner 1968, Brehmer et al. 1969, Hall 1972, Cole 1973, Ertl and Tomajka 1973, Profet and Ransom 1974, Marker 1976b, Pennak and Lavelle 1979, Sumner and Fisher 1979, Gregory 1980). Upstream-downstream techniques were mainly used prior to the collection of data for the present study (1973-1975). The most frequently examined parameters were light and temperature, but included chlorophyll content or AFDW of periphyton, current, organic content of sediments, nutrients, and recently grazing (Hunter 1980, Gregory 1980, Kesler 1981).

In the present study, parameters examined in relation to NCP, GCP, CR, and NDM included stream order, temperature, light, and AFDW

of the sediments (detrital, epilithon and total). Cusing (1967) studied many parameters over an annual period from periphyton communities developed on artificial substrates, but none of the above studies reported in situ data for as extensive a set of parameters over an extended period. Regression analyses were completed for each parameter listed above against each dependent variable (NCP, GCP, CR, NDM) on an annual average basis, as well as by site. Individual half-hour rates of NCP and CR (parameters measured directly in the field) were matched with corresponding light and temperature intervals and run individually and together in multiple regression. The independent variables are discussed separately, but a summary of the regressions is available in Appendix E.

Stream Order

The order system, as defined by Strahler (1957) classifies streams on a physical basis and is convenient for comparison of data particularly within a given watershed. Hynes (1970) suggested heavier usage of this format for characterization of streams. Investigators have begun to relate results on an order basis. Cummins (1974, 1975b, 1977) and Vannote et al. (1980) related various components of stream community structure and function to an order scale. Mahan (1980) found a relationship between amounts of CPOM input to woodland streams, Naiman and Sedell (1979a) investigated benthic organic matter on an order basis and Seyfer and Wilhm (1977) found relationships between periphyton species composition, diversity, and biomass to be a function of stream order.

Regressions with stream order as the independent variable

indicated a significant ($P < 0.01$) positive relationship for all parameters with $n = \sim 100$ for each case (Appendix E; Table 14). Multiple correlation coefficients (R) ranged from 0.52 for CR to 0.74 for NCP, and F ratios (test for significance=1; higher, more significant) were high especially for GCP and NCP (Table 14; Appendix E). The correlation between stream order and each dependent variable was always highest, which indicates the importance of geomorphology on the functional aspects of stream communities. It is intuitive that as streams widen they receive more light and higher rates of primary productivity would result unless factors such as turbidity, or chemical/physical perturbations were involved. NCP and GCP had the highest F ratios (Table 14), which would be most directly related to light. Rates of CR, although significant, were least affected by stream order, and illustrated a lesser dependence on location (i.e. light availability) than the photosynthetic processes and a heterotroph dominated CR. NDM, influenced by rates of CR, had a lower F ratio, but still indicated a strong relationship with order ($F = 74$; Table 14).

Light

Various authors have eluded to the importance of light on aquatic primary productivity in the field (Butcher et al. 1930, Calvert 1933, McConnell and Sigler 1959, Profet and Ransom 1974, Sumner and Fisher 1979, Hornick et al. 1981), but few studies have carefully examined the relationship (Kobayasi 1961, Stockner 1968, Hunding 1971, Cadee and Hegeman 1974).

Marker (1976b), using Tygon cloth to shade chambers (9,000 lux

versus 27,000 lux lighted) illustrated a 30% decrease in primary productivity. Gregory (1980) artificially lighted a section of a wooded stream (10,000 lux) and significantly increased productivity of a riffle section. The effects of clear cutting and channelization on photosynthesis have been shown by Gelroth and Marzolf (1978) and Gregory (1980). Pennak and Lavelle (1979), studying in situ NCP in mountain stream riffles, found no correlation between NCP and light intensity, but the results were probably influenced by very low periphyton standing crops.

Regression analyses from Augusta Creek communities indicated light was the second most important parameter affecting individual NCP and average GCP, NCP, and NDM; outranked only by stream order (Table 15; Appendix E). F ratios and R values were high and significant in all cases ($P < 0.05$; Table 15). Average data ($n = \sim 100$) with correlation coefficients ranging from 0.52 to 0.57 and F ratios ranging from 36 to 46, indicated the importance of light on levels of GCP, NCP, and NDM within the Augusta Creek drainage, GCP had the highest R (0.57) and F ratio (46.0), but all were similar (Appendix E; Table 15). When individual measures of NCP were used in regression analyses ($n = 666$ and $R = 0.6$ with a high level of significance; Table 15) and when multiple regression with temperature and light was completed (Table 16) $R = 0.6$ with light R value = 0.597 and temperature 0.005. The Augusta Creek correlation coefficient for light and NCP, although lower than those of Cushing (1967) and Stockner (1968) for lotic periphyton communities ($R=0.8$), included values from heterotrophic as well as autotrophic sites. Pamatmat (1968) and Gargas (1970) cited light as the most important factor

influencing community metabolism of marine microbenthos (F ratios = 72-98), as did Littler (1973) in coral reef communities, and Hunding and Hargrave (1973) in freshwater littoral zones.

The sites trend in F ratios reflected productive capacity. Lower values were from Smith and B Avenue, while the Upper 43rd, Nagel and Kellogg Forest F ratios were greater than one, however, on a site basis values were not significant in most casts (Table 15). At autotrophic based sites the effects of light were greater on GCP and NDM than NCP (Table 15). Values of GCP and NDM were calculated using estimates of CR; one is a positive influence (GCP) while the other is negative (NDM) and both increased, which indicates some unmeasured parameter such as grazing losses may have been involved. Kesler (1981) reported Chironomus scutellaria may consume 3 to 70% of the NCP, while Hunt (1980) and Gregory (1980) found that snails could effectively reduce periphyton communities. Populations of grazer organisms, including Hydroptila, Neophylax, Glossosoma, Helicopsyche (Trichoptera:caddisflies), Stenonema (Ephemeroptera:mayflies), Psephenus (Coleoptera:beetles) and Ferrissia (Gastropoda:snails) were common, especially at the Nagel Site and observations of grazing rates by D. Hart (personal communication, Kellogg Biological Station) indicated active cropping of periphyton at the Nagel Site.

The relationship between light intensity and rates of photosynthesis is not linear over a large range of light values. Light saturation and photoinhibition often occur at higher light intensities in phytoplankton communities (Ryther 1956a, Verduin 1956, Pamatmat 1968, Marker 1976b, Ganning and Wulff 1970. Light saturation occurred at approximately 20,000 lux for combined sites of Augusta

Creek (Appendix F; Figure F - 1). Except for Smith Site, saturation ranges were very similar: B Avenue (n=677) 20,000 lux, Upper 43rd (n=220) 24,000 lux, Nagel (n=571) 15,000 to 20,000 lux, and Kellogg Forest (n=242) 18,000 to 20,000 lux (Figures F 1-6). Rates of NCP, and likely algal standing crops, were very low at the Smith Site and few measurements of NCP were made above 20,000 lux (Figure F - 2), therefore, resolution of light saturated photosynthesis was not possible. These saturation levels are within the range reported for marine phytoplankton (5,000 to 30,000 lux; Ryther 1956a), and lentic benthic algae (10,000 to 12,000 lux; Hunding 1971, Lester et al. 1974, Colijn and Buurt 1975), and natural and artificial streams (4,000 to 62,000 lux; Kobayasi 1961, McIntire et al. 1964).

Photoinhibition was not observed at any of the sites (Figures F 2-6), which was not surprising, as it has not been reported in lentic periphyton communities (Pamatmat 1968, Ganning and Wulff 1970, Hunding 1971, Gallagher and Daiber 1973, Littler 1973, Cadee and Hegeman 1974, Colijn and Buurt 1975). In artificial stream developed periphyton communities, McIntire et al. (1964) and McIntire and Phinney (1965) found no photoinhibition and Marker (1976b) noted no photoinhibition from an in situ study. The large number of in situ cases examined from autotrophic and heterotrophic sites in the Augusta Creek watershed reinforced these noted examples.

The effects of temperature on light saturated photosynthesis are illustrated in Appendix F (Figures F 7-11). The most linear of these plots (0 - 5 C) indicated light saturation at 18,000 lux (Figure F - 7, n=414). At temperature intervals 5 to 10 C, 10 to 15 C, 15 to 20 C, and 20 to 25 C light saturation occurred between 20,000 to 25,000

lux (Figures F 8-11). Kobayasi (1961) found seasonal shifts in light saturation from 8000 lux in a winter diatom community to 15,000 lux in the summer Cladophora dominated community. As indicated by Ryther (1956a) light saturation levels vary for various algal taxa, and the shift observed by Kobayasi (1961) and the slight increase at 15 - 20 C (Figure F-10) at Augusta Creek sites may have been due to changes in species composition rather than temperature. The influence of temperature on photosynthetic activity, studied by Rabinowich (1951) and Jørgensen and Steemann Nielsen (1965, 1968), discussed in McIntire et al. (1964) and Hunding (1971), indicated the rapid increase portion of the activity curve to be due to photochemical processes independent of temperature, while the saturated portion of the curve fluctuated depending on temperature effects on the photosynthetic enzymes. Although rates of NCP increased with temperature, similar levels of light saturation were indicated over the temperature range naturally encountered by Augusta Creek communities (0 - 25 C) and illustrated the complexity of photosynthetic responses to more than one variable. Light was the primary factor regulating primary productivity in woodland streams and based on light-saturated photosynthesis levels and average daily light of 12,000 to 13,000 lux, amounts of NCP at Smith and B Avenue would be limited. Reduced levels of NCP were documented by in situ measurements at these two sites compared to the open and shaded larger order study reaches (Figure 15).

Temperature

The effects of temperature on organisms and metabolic processes have been extensively investigated, and Q_{10} values have been calculated

for process of organisms from bacteria to mammals. The relationship between temperature and community metabolism in streams, however, has not received much attention. In aquatic systems the effects of temperature on CR was investigated in marine tidal flats (Pamatmat 1968, Gallagher and Daiber 1973, Cadeé and Hegeman 1974), and freshwater littoral zones (Hargrave 1969a, 1969b; Edberg and Hofsten 1973) with all investigators reporting temperature to be an important controlling factor. The effects of temperature on community productivity have been studied, but mainly in lentic systems where a positive correlation has been indicated, but of lesser importance than the effects of light (Gargas 1970, Hunding 1971, Adams and Stone 1973, Ertl and Tomajka 1973, Gallagher and Daiber 1973, Cadeé and Hegeman 1974, Colijn and Buurt 1975).

The average data (n=100) indicated a positive relationship between temperature and all parameters with R values ranging from 0.64 for CR to 0.33 for NCP and F ratios of 12 to 70 (Appendix E; Table 17). These values were generally lower than the values for light, but still significant at the $P=0.01$ level (Tables 15, 17). While CR had the lowest correlation with light, it was most strongly correlated with temperature. Hargrave (1969b), Ertl and Tomajka (1973), and Cadeé and Hegeman (1974) reported positive correlations between levels of GPP and temperature in lentic systems. The R of 0.5 for temperature and GPP from intertidal flats of the Wadden Sea was similar to the 0.41 R for GCP and temperature from Augusta Creek sites (Table 17).

Individual rates of NCP (n=1957) indicated a significant correlation with temperature ($R = 0.18$; F ratio = 67.1). However,

this was much less than the regression with light ($R = 0.06$; F ratio = 4089.7). Individual rates of CR ($n=1189$) had an R value of 0.52 and F ratio of 447.1, which indicated a highly significant relationship (Table 17). When run with light in multiple regression, temperature had an $R = 0.43$ in contrast to $R = 0.24$ for light (Table 16). Together ($n=1968$), or on a site basis, there was no evident relationship between NCP and temperature (Figures G 7-12).

Considering the 1189 points in Figure G - 1, rates of CR generally increased linearly with increasing temperature, especially if data from Smith and B Avenue Sites are omitted. Both of these sites showed constant CR regardless of temperature (Figures G-2, G-3). The lack of correlation between temperature and CR at Smith Site was evident from the regression analyses (Table 17). Assuming that these communities are heterotrophic, one would expect CR to increase with temperature as reported for bacteria (Brock 1966). The consistency noted at the first order sites was related to the comparatively low epilithon standing crops. Beyers (1962) recorded that in experimental microcosms temperature affected CR until a balanced ecosystem had developed. He related this to the multiplicity of metabolic pathways at work within the community, which easily adapted to changing conditions. Therefore, the consistency may be related to establishment of a dynamic equilibrium as rates of CR varied little over the seasons.

At the open Upper 43rd and Nagel sites with well developed epilithic communities, a direct relationship existed with temperature (Figures G-4, G-5). Levels of CR correlated with epilithon development, ranking from low to highest rates and development:

Smith, B Avenue, Kellogg Forest and Nagel (Kellogg Forest = Nagel) (Table 9). Although temperature was important in controlling rates of CR, a community must be present to respire, and at Smith Site low CR indicated low microbial development.

On a site basis a significant relationship with temperature was not evident for any parameter measured at Smith Site, while at B Avenue CR, GCP and NDM were correlated with temperature (Appendix E, Table 17). Cooler temperatures probably influenced algal development at these sites (Smith \bar{x} 9.5 C, B Avenue \bar{x} 8.7 C), but temperature ranges (0 - 25 C) included periods in which diatom growth abounded (Table 10). The higher temperatures occurred during maximum canopy cover, therefore, complicating interpretation of development patterns. Diatoms were visually present at B Avenue, and GCP and NDM were correlated with temperature at this site.

At the Nagel, Upper 43rd, and Kellogg Forest sites, CR was again the most obviously correlated parameter with temperature; GCP was the only other significantly correlated parameter ($P = 0.05$; Appendix E; Table 17). NCP levels were more positively influenced by temperature at these open sites (Figures G 10 - 12), as indicated by increased R values and F ratios (Table 17). This relationship indicated that temperature may have been limiting epilithon development at the shaded first order sites when light was available for increased levels of primary productivity. Adams and Stone (1973) reported seasonal differences in NCP of Cladophora to be closely related to temperatures. The importance of temperature on rates of CR, GCP, and NDM, possibly through CR mediation on GCP and NDM, or some unknown influence such as community composition and species temperature

optima, or total epilithon development and stability was evident at sites of Augusta Creek.

Detrital-Ash-Free Dry Weight

The question of the effects of detrital standing crops on CR of communities has been addressed in lentic and lotic systems (Nelson and Scott 1962, Hargrave 1969b, Edberg and Hofsten 1973, Göthberg and Karlström 1975). Studies relating productivity to AFDW of detritus have not been reported.

The high values of P make it evident that detritus had little effect on community metabolism at sites of Augusta Creek (Table 18). Few of the F ratios were greater than one, which also indicated there was little influence on average rates or on an individual site basis (Table 18; Appendix E). These ratios ranged from 0.01 for average GCP to 1.3 for average NDM and on a site basis from 0.02 for NCP at B Avenue to 3.24 for CR at the Nagel Site. There were no clear patterns established as values greater than one were for different parameters. The correlations between parameters and detritus were weak, and measurement of detrital standing crop was not of value in predicting rates of community metabolism at riffle sites of Augusta Creek.

Epilithon

Epilithon has been characterized in the literature mainly by estimates of biomass obtained from chlorophyll extraction (McConnell and Sigler 1956, Wetzel 1963, Duffer and Dorris 1966, Grzenda et al. 1968, Bowbówna 1972, Cadee and Hegeman 1974, Helan et al. 1977, Seyfer and Wilhm 1977, Sumner and Fisher 1979, Bush and Fisher 1981). Dry weight and AFDW determinations on artificial substrates have also been

used (Cushing 1967, Edberg and Hofsten 1973, Helan et al. 1973, Calow 1975, Naiman 1976, Seyfer and Wilhm 1977). These above studies indicated variable correlation between biomass and community metabolism. However, these studies were aimed at determining autotrophic colonization rather than the entire assemblage including detritus. Madsen (1972) found the epilithon of shaded Denmark streams to be detrital dominated, and Calow (1975) found epilithic detritus to be a high quality food for macroinvertebrates. Perkins and Kaplen (1978), reported epilithon to be 76% detritus and further characterized this segment to be accumulated autochthonously produced diatom stalks. Clearly, detritus is a portion of the epilithon and will be involved in any in situ measurements of community metabolism and the impact of the intact assemblage is of importance in the function of stream ecosystems regardless of the composition.

On an annual average basis, a significant positive relationship existed between epilithon development and all dependent variables (Table 19). F ratios ranged from 7.8 for NDM to 17.6 for NCP (Table 19). The F ratios for epilithon followed stream order and light in order of magnitude (Appendix E); these values were much more significant than estimates of detrital AFDW. Correlations ranging from $R = 0.28$ to 0.8 have been reported for biomass and primary productivity (Cadee and Hegeman 1974, Ertl and Tomajka 1973). Augusta Creek values of $R = 0.42$ NCP and $R = 0.39$ GCP (Table 19) are within this range. Various relationships have been demonstrated using chlorophyll a extractions as an estimator of biomass (Wetzel 1963, Schindler et al. 1973, Sumner and Fisher 1975, Marker 1976b, de laCruz and Post 1977, Bush and Fisher 1981). While chlorophyll estimates may

reflect productivity changes, using epilithon estimates the entire community is included and integrated.

The effects of epilithon development on CR and NDM have not been examined by many investigators. However, Bush and Fisher (1981) reported increased CR with increased biomass in a desert stream (Arizona). The relationships indicated by regressions from Augusta Creek riffles were not high, but ranked above detrital standing crop estimates (Table 19). For individual sites several F values were greater than one, but few regressions were significant ($P = 0.05$). This indicates a stabilization in epilithon development at a site, with site differences reflected in the average epilithon and metabolic capacities. Dynamic changes in biomass per day would not be expected dealing with large initial epilithon weights (compared to cell or detrital weights). Rates of metabolism oscillated with changes in physical factors, therefore, only when averaged over the annual period would these correlations become obvious. Average integration is further supported by the higher correlations at Smith site where epilithon levels were lower and changes were more readily detected.

Sites

Examining the regression data (Appendix E) for each dependent variable stream order was the most important factor influencing community metabolism. Of the variable parameters light was by far the most important parameter for all facets of community metabolism except CR where temperature was most important.

At the sites controlling factors varied (Table E - 3). The highest and only significant correlation and F ratio was epilithon at

the Smith Site, which illustrates the importance of even small amounts of detrital or algal accumulation. At the B Avenue Site the only significant relationships were with temperature for CR, GCP, and NDM, which indicated a bacterial dominated community. Upper 43rd Site had significant correlations between GCP and CR with temperature, Nagel had temperature correlating with NCP, CR, GCP and NDM and light with GCP, while the Kellogg Forest had significant regressions for GCP, CR, and temperature and NDM with light and epilithon. Temperature on a site basis was the influencing factor on average rates of community metabolism and only when individual rates were examined was the overwhelming importance of light evident.

Particle-Size Community Metabolism

The impact of various inorganic and organic particle-size distributions within sediments on community metabolism in lotic systems has received little attention (Minshall et al. 1982). McConnell and Sigler (1959) and Marker (1976b) indicated that the larger inorganic particles contained approximately 95% of the algal biomass based on chlorophyll extractions, which indicated larger particles more suitable for algal colonization. Nelson and Scott (1962) studying CR rates in various sections of the Oconee River, Georgia, using the upstream-downstream technique, found CR to be insignificant on shifting sand substrates. This technique does not allow separation of discrete particle-sizes or detritus from inorganic sediments.

Electron and epifluorescence microscopy of epilithon of small stones indicated a prevalence of detritus (Madsen 1972) and Suberkropp

and Klug (1974) illustrated that as detrital particles decreased in size the major colonization shifts from fungal hyphae to bacteria. In their micrographs algae (diatoms) were also present. It is of both theoretical and applied interest to examine the metabolism of various sediment particle-sizes and their contribution to total community metabolism.

The activity on an AFDW basis ($\mu\text{O}_2 \text{ g}^{-1}$) of various particle sizes may be compared and when converted to $\text{g O}_2 \text{ m}^{-2}\text{d}^{-1}$ the relative contribution of particles to overall community metabolism can be partitioned and the trends compared to in situ measurements (Appendix H). Comparisons of Gilson metabolism estimates to in situ rates of NCP, GCP and CR m^{-2} indicated parameters to generally be greater when estimated by the former method (Table 20). This trend, especially for macroinvertebrate-free sediments, may indicate the inadequacy of short term estimates, extrapolation to an areal basis assuming all layers of epilithon metabolize at equal rates, particle-sizing and assuming all particles behave the same in situ where depth of the particle would be of importance, or exposure through particle-sizing of surfaces to higher oxygen concentrations with subsequent increased activity of the flora, especially facultative anaerobes. However, the Gilson estimates are of value for comparative purposes and particle-size analyses.

Particle-sized estimates of community metabolism (AFDW basis)

NCP for detritus ranged from $-319.7 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ at B Avenue in August to $+1687.6 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ at Upper 43rd in June; $0.45 \mu\text{m}$ particles were always most active (Table H-1; Figures 26, 27). Annual averages

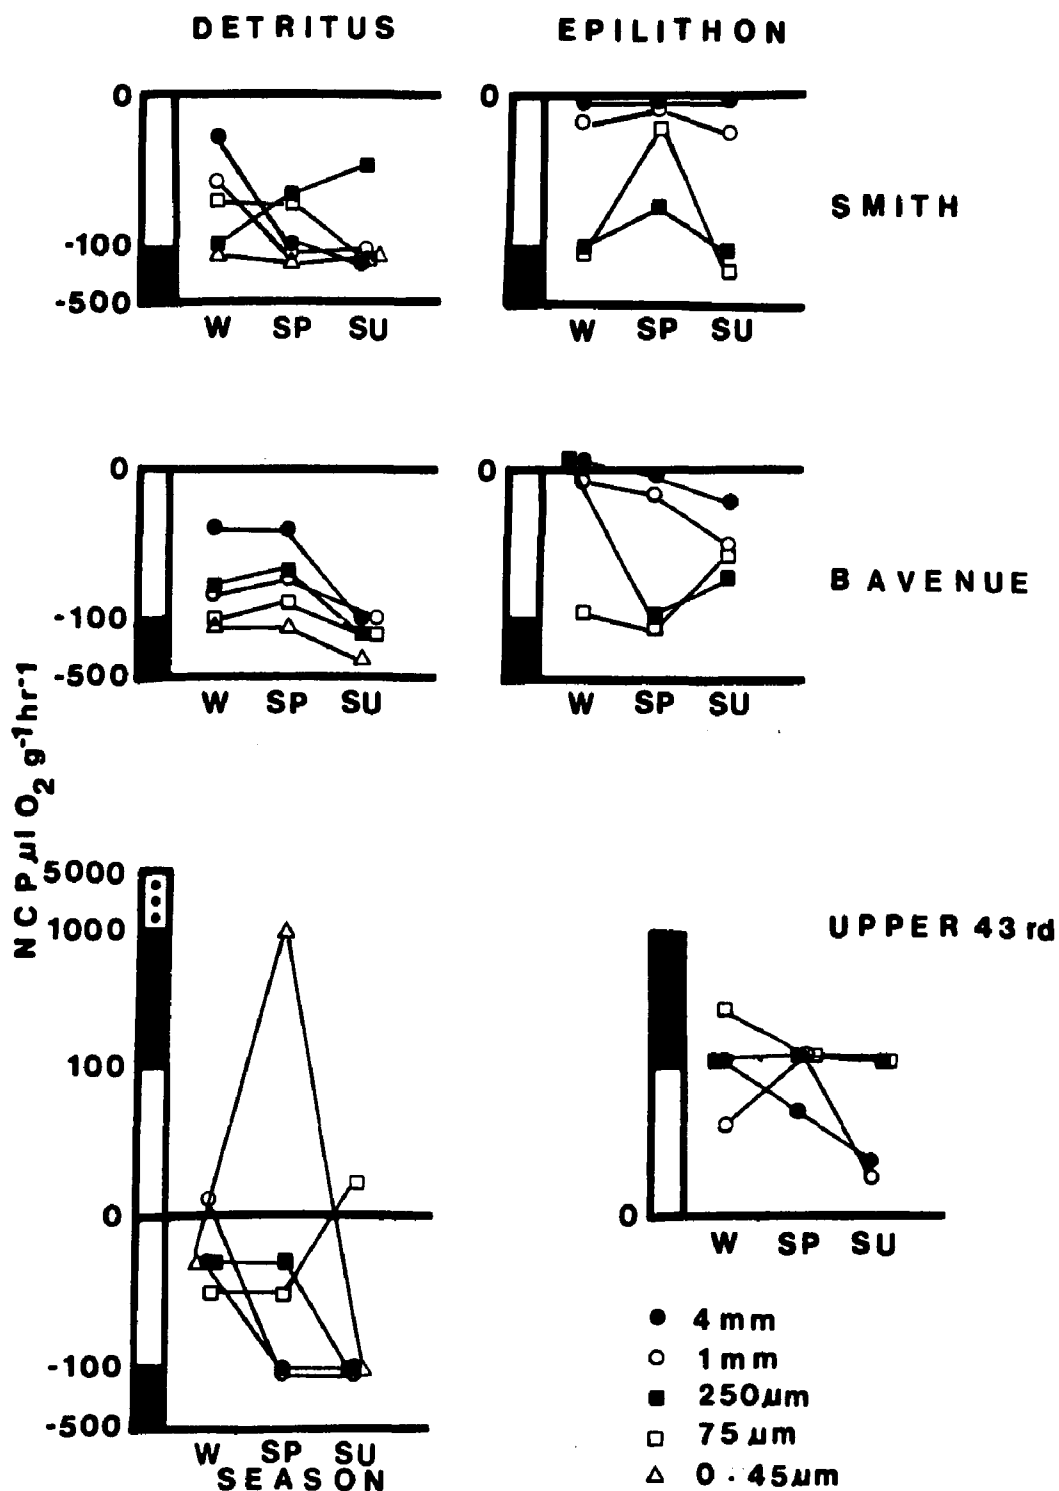

Figure 26. Estimates of NCP from particle sized detritus and epilithon communities from Smith, B Avenue and Upper 43rd riffle sites of Augusta Creek, Kalamazoo County, Michigan (1974-1975).

Figure 27. Estimates of NCP from particle-sized detritus and epilithon communities from Nagel and Kellogg Forest riffle sites of Augusta Creek, Kalamazoo County, Michigan (1974-1975).

for particle-sizes ranged from -213.3 to $+485.3 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ at B Avenue and Upper 43rd, respectively (Table 21). The striking features of detrital NCP included negative values for the majority of particle sizes during all seasons, with least negative values of NCP generally during the February diatom bloom. The only positive value was during June at the Upper 43rd Site. Similar seasonal trends existed for all sizes within sites (Figures 26, 27). Comparing average rates of NCP between sites, B Avenue and Smith values were consistently more negative than the autotrophic sites (Table 21). Ranking the particles on increasing levels of NCP at each site (Table 22) there were no clear patterns within particle-sizes, but ranked by total average NCP, the $0.45 \mu\text{m}$ detritus had the only positive value, while the others were similar with the $75 \mu\text{m}$, which were lowest in autotrophic colonization (Tables 21, 22).

Estimates of epilithon NCP ranged from -321.0 to $+2174.2 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for $75 \mu\text{m}$ mineral sediments in August at Smith and 4 mm sediments in March at the Kellogg Forest Sites, respectively (Appendix H; Figures 26, 27). Averages ranged from $-155 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for $75 \mu\text{m}$ particles to $+752.9 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for 4 mm gravel at Kellogg Forest (Table 21). Based on rates of positive NCP, epilithon of all inorganic fractions at Upper 43rd were colonized by autotrophic organisms during all seasons, as well as the majority of the Nagel and Kellogg Forest particles (Figures 26, 27). Lowest rates of NCP at these sites occurred in August, while maxima were scattered in occurrence (Figures 26, 27). The heterotrophic sites had little algal colonization, but greater NCP occurred on these sediments than the detrital segments, especially in the 4 and 1 mm inorganic fractions.

Sites ranked by average epilithon NCP in increasing order were: Smith, B Avenue, Nagel, Upper 43rd, and Kellogg Forest (Table 21). Obvious differences were evident between the heterotrophic headwater sites and the open sites of Augusta Creek. Ranked particle-sized epilithon NCP (Table 22) showed variable results with larger sizes autotrophically colonized most heavily at Smith, B Avenue, and Kellogg Forest, while smaller particles at Nagel and Upper 43rd had the highest values of NCP. Averaging sites, the two extremes in particle-size had the highest rates of NCP with 1 mm particles lowest in activity (Table 22). Heaviest autotrophic colonization of larger particles has been shown by other investigators (McConnell and Sigler 1959, Duffer and Dorris 1966, Marker 1976b). Although primary productivity has not been reported on discrete particle sizes in the literature, Gargas (1970) reported the epipsammon to contribute 60 to 83% of the primary production of marine littoral sediments as compared to detritus and noted Gronsted (1960, 1962) found similar results in sediments of the Wadden Sea and Danish fjords. These studies, with autotrophic colonization on fine particles (sands) are similar to the increased levels of NCP on the 75 μm inorganic sediments reported in this study.

Partitioned CR ($\mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$) results for sediments indicated the detrital particles had higher rates of CR than the inorganic sediments. Higher (40 to 90%) detrital than inorganic sediment CR has been reported by Teal (1962) and Hargrave (1972) from lentic systems. The 4 mm and 1 mm inorganic particles from Augusta Creek approximated 35% of the detrital CR, but that of smaller particles (250 and $\mu\text{75 m}$) was approximately equal (104 and 109% respectively). As particle-size

decreases, surface area to volume increases and floral shifts from fungi to bacteria were noted by Suberkropp and Klug (1974), which may have accounted for increased rates of metabolic activity on the finer particles at Augusta Creek sites. However, Nelson and Scott (1962) found CR to be insignificant on shifting sand bottoms, which indicates a complex relationship between particle-size and CR, dependent on the location and stability of small particles within the sediments. Total inorganic CR averaged 70% of total CR at Augusta Creek riffles.

Detrital CR ranged from $15.1 \mu\text{O}_1 \text{ g}^{-1}\text{h}^{-1}$ for 4 mm fractions from Nagel Site in March to $738.8 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for 0.45 μm Upper 43rd detritus in June, while particle-size specific CR averaged over the early spring to late summer period ranged from $34 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for 4 and 1 mm detritus to $351 \mu\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for 0.45 μm components, both at Upper 43rd (Appendix H; Table 21). The lowest rates at all sites were during the early spring; they increased during early summer and generally attained maxima in late summer (Figure 28). The ultrafine particulate organic matter (0.45 μm category = UPOM) rates of CR were consistently highest at all sites with most other particles similar and lower in rates of CR (Figure 28). The highest average rates were from Upper 43rd detritus followed by Kellogg Forest, B Avenue, Smith and Nagel (Table 21). The average activity by particle size (Table 22) indicated 0.45 μm detrital particles had the highest rates of CR followed by 4 mm particles with 75 μm , 1 mm, and 250 μm detrital particles similar. These data are unlike those of Fenchel (1970) and Hargrave (1972) who found detritus CR rates inversely related to particle size. Based on surface to volume ratios of particles an inverse relationship may be expected, however, this premise would be

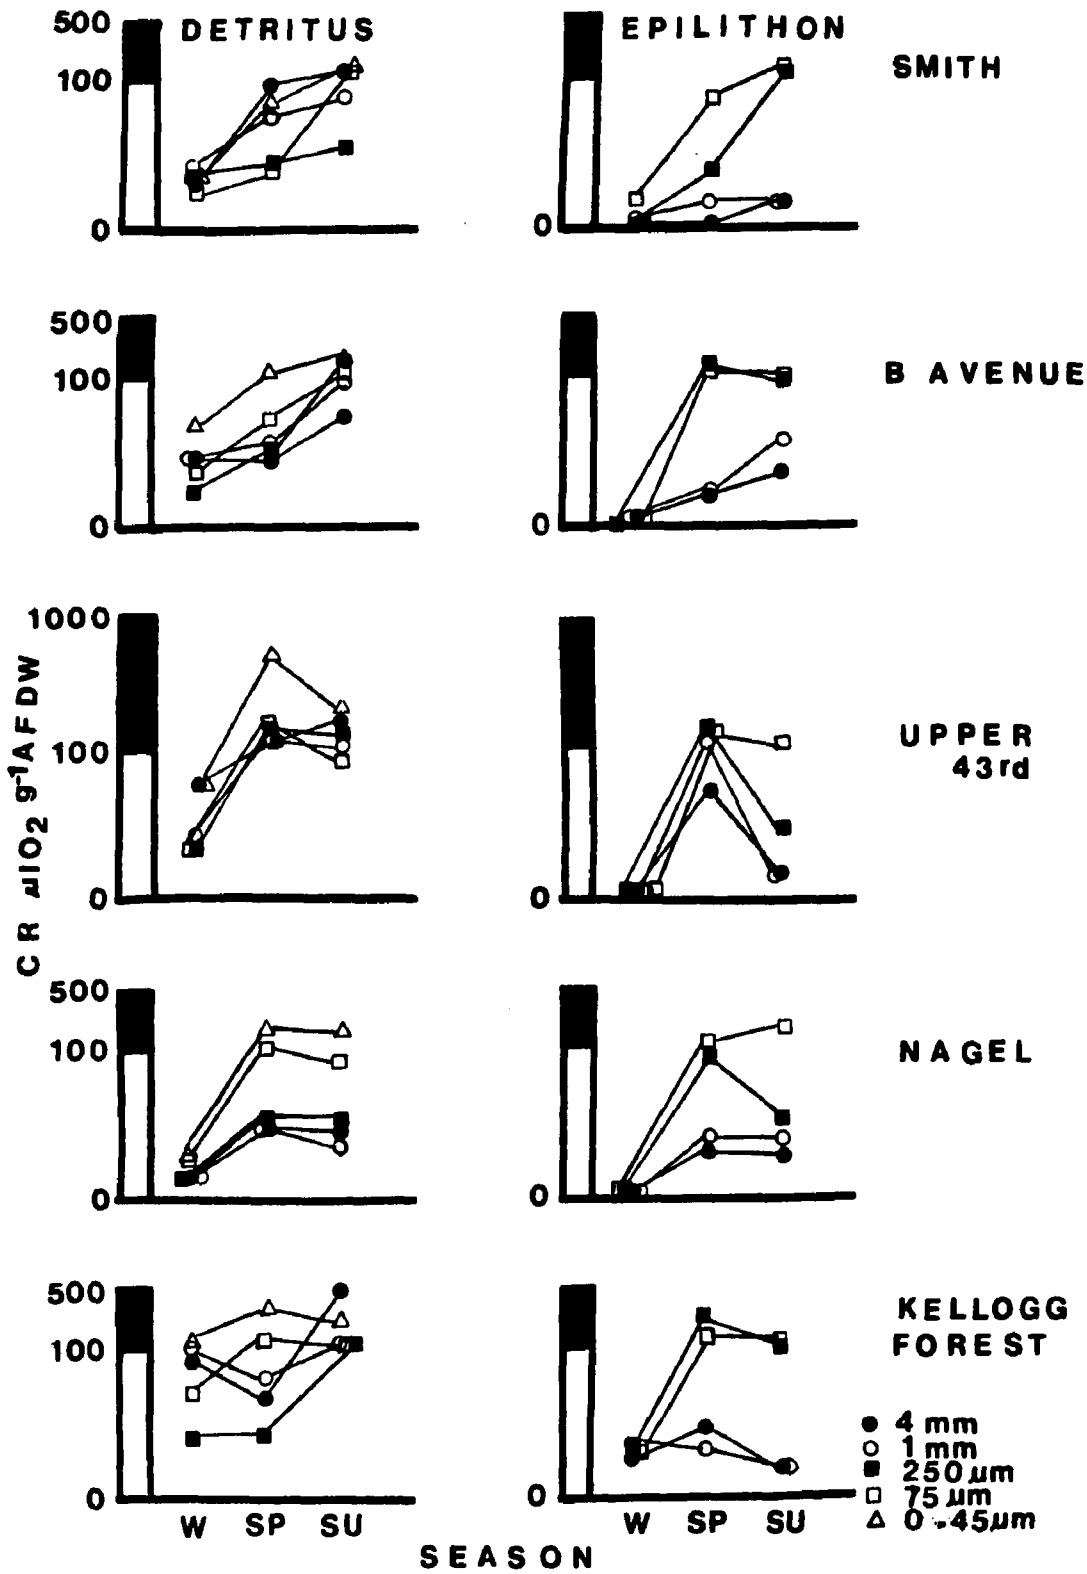

Figure 28. Estimates of CR from particle-sized detritus and epilithon communities from selected riffle sites of Augusta Creek, Kalamazoo County, Michigan (1974-1975).

based on equal colonization of surfaces by a similar flora (i.e. bacteria). In heterogeneous layered substrates differences would be expected in types of colonizers (i.e. autotrophic-heterotrophic components) and particle location (i.e. light availability).

Epilithon CR was also lowest during spring periods; increased during early summer; and remained stable at Smith and B Avenue Sites during the summer, but decreased at the Upper 43rd, Nagel and Kellogg Forest (Figure 28). The decrease at the autotrophic sites resulted during the period of algal senescence; detrital CR increased at the same time indicative of algal inputs to the detrital pool (Edberg and Hofsten 1973).

Rates of epilithon CR ranged from nondetectable for 250 μm sands at Smith, Nagel, and Upper 43rd Sites in early spring to 214.4 $\mu\text{M}\text{O}_2 \text{ g}^{-1}\text{h}^{-1}$ for 75 μm sands in June at the Kellogg Forest (Appendix H). Averaged by site, the highest CR was at the Kellogg Forest and Upper 43rd Sites with B Avenue and Nagel Sites approximately equal and Smith lowest (Table 21). The similarity of B Avenue and Nagel epilithon CR would indicate similar levels of colonization, but the percent composition of autotrophs must have varied significantly based on the NCP values (Tables 9, 21). Ranked by increasing activity, the epilithon CR patterns followed the inverse relationship with particle-size proposed for detritus by Fenchel (1970) and Hargrave (1972). Comparing particle-sizes, a similar trend existed; averages for the 75 μm sands were the most active while the 1 mm were lowest at all sites (Table 21). Overall on a weight basis, detritus had higher CR and lower NCP than epilithon.

Particle-sized estimates of community metabolism Areal basis)

On an areal basis, as on a weight basis, the autotrophic colonization was in the epilithon community, but on an areal basis, especially for epilithon, general trends were similar to in situ. This agreement further substantiates the magnitude of epilithon biomass in riffle sections. Average detrital NCP m^{-2} , as on a weight basis, was generally negative with the highest and only positive value at Upper 43rd for 0.45 μm detritus (Table 23). The lowest average values were also for this segment at B Avenue and Smith Sites (Table 23). Averaged for particle-size, the lowest values of NCP were for the UPOM and highest for the CPOM fractions, which differed from a weight basis where UPOM had highest average values (Tables 21, 23). When particles were ranked by site for NCP (Table 24) the averages had a similar pattern to a weight basis, but generally there was direct relationship between rate and particle size not evident on a weight basis (Tables 22, 24). Areal ranked sites were identical to biomass (AFDW) (Tables 22, 24).

The highest average NCP rates were from the epilithon of Upper 43rd 4 mm inorganic sediments, while the lowest rates were from 75 μm sands from the Smith site (Table 23). On an average particle-sized basis contributions of the 4 mm stones were highly separated from the other rates of NCP; the 75 μm sands had the lowest activity. On the weight basis the 75 μm fractions had high levels of activity (Tables 21, 23). Ranking sites by NCP m^{-2} (Table 23), Smith was lowest followed by B Avenue, Kellogg Forest, Nagel and Upper 43rd, while on the weight ranking the autotrophic sites shifted to Nagel, Upper 43rd, and Kellogg Forest. This shift illustrates the effects of epilithon

development and detrital content of the sediments. In situ estimates of average NCP ranked more closely with epilithon than detrital values (Tables 9, 21, 23).

Even though CR estimates g^{-1} AFDW detritus were consistently higher than for epilithon (Table 21), when expressed on an areal format the reverse was true and the impact of the epilithic community established (Table 23). UPOM for which there is no inorganic counterpart had higher CR than all of the inorganic fractions except 4 mm stones, noting the importance of the two extremes in particle-size and sediment types in the autotrophic-heterotrophic balance of riffle sections. Detrital CR was highest (average m^{-2}) at the Kellogg Forest for UPOM and lowest at Nagel Site for 4 mm pieces. Averaged by particle-size the highest and lowest components remained the same and were similar to a weight basis. Areal particle-size ranking indicated the generally accepted trend of CR inversely related to particle-size (Fenchel 1970, Hargrave 1972, Naiman and Sedell 1979b). On a weight basis this pattern was characteristic only of the Nagel site (Table 22).

Epilithon CR was higher than detrital on an area basis, and even the lowest Smith epilithon had higher CR m^{-2} than all except B Avenue and Kellogg Forest detrital particles (Table 23). On an average the 4 mm particles dominated CR at all of the sites and 75 μm sands contributed the least to epilithon CR. These average trends were characteristic of all sites with a direct relationship noted between particle-size and CR (Table 23). On the weight basis (Tables 21, 23) the reverse was true. This reversal indicated a more active, but lesser developed microflora on the sands.

When extrapolated to an areal basis, negative values of NCP, GCP, and NDM were consistently measured on detritus at the Smith Site with the 0.45 μm fraction predictably lowest; the others were significantly different and closely grouped (Figure 29). The 4 mm detritus, indicating some algal colonization, had the highest rates of NCP and the lowest rates of CR. CR was highest in the 0.45 μm fractions and increased with seasonal temperatures as did in situ CR (Figure 16). The consistently low NDM and P/R ratios of both detrital and epilithon fractions indicated heterotrophic colonization of all substrates and the heterotrophic character of this first order site (Figures 17, 18, 29, 30).

Within the epilithic community, as well, little autotrophic potential existed (Figure 30). The only positive value for NCP was on 4 mm substrates during the February diatom bloom, which indicated a more diverse flora was present. The 75 μm sands had the least negative and most consistent levels of NCP, but as evidenced by GCP values, only in June rose above baseline in primary productivity. The 1 mm and 75 μm inorganic sediments had maxima in GCP just after the major diatom bloom which may be the result of diatom community changes within the sediments from the Meridion - Diatoma bloom forms to smaller motile migratory forms which may colonize smaller sediments. However, only taxonomic analyses could substantiate this hypothesis. The comparison of particle-size specific epilithon NCP trends to in situ measurements indicated similar patterns as did the detrital component, which reinforced the dominance of heterotrophic processes with the riffle community.

B Avenue detritus, like Smith, had negative values of NCP, GCP,

SMITH - DETRITUS

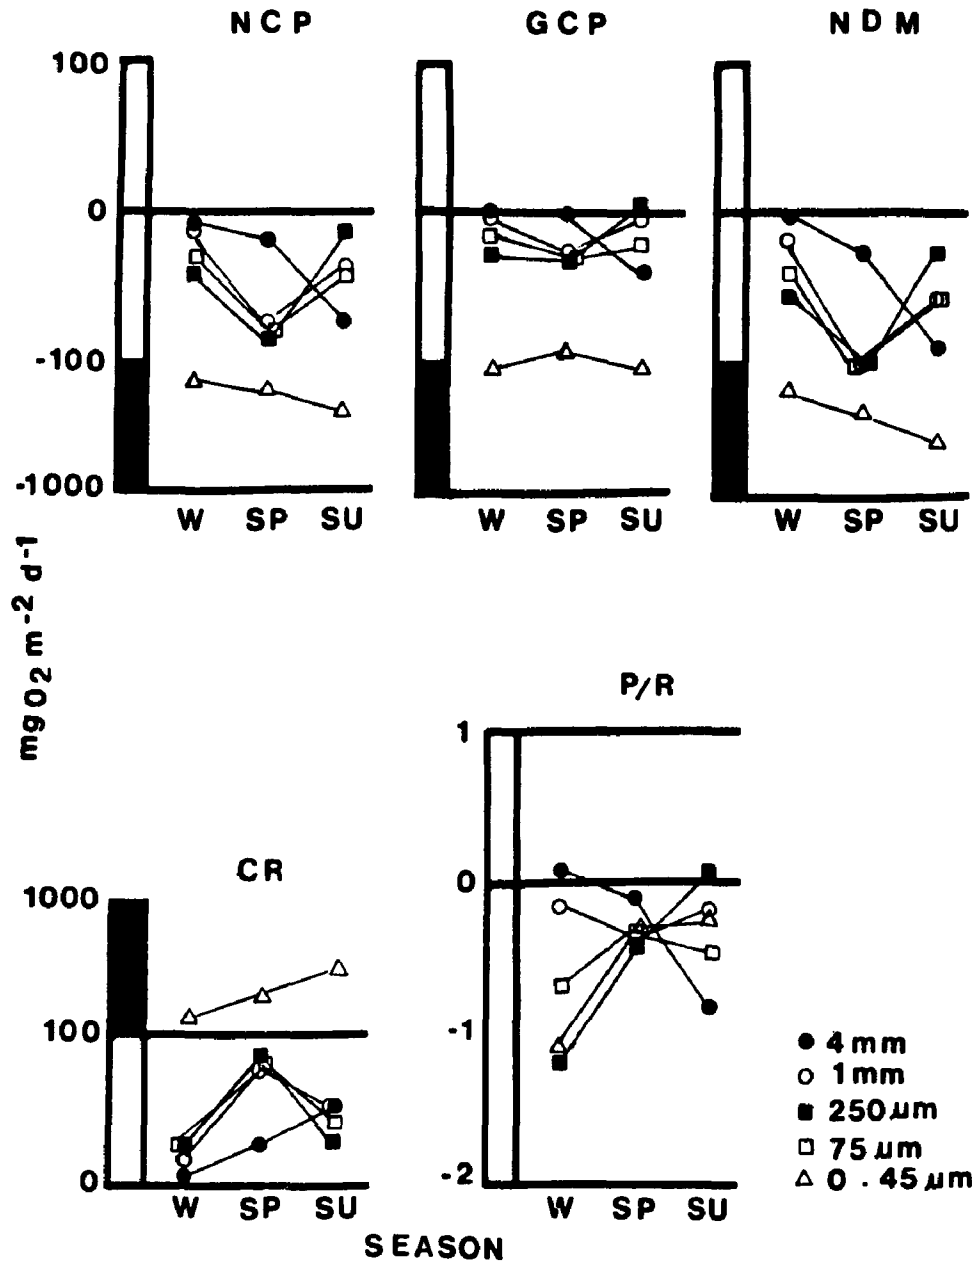

Figure 29. Estimates of particle-sized community metabolism of the detrital component of Smith riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

SMITH - EPI LITHON

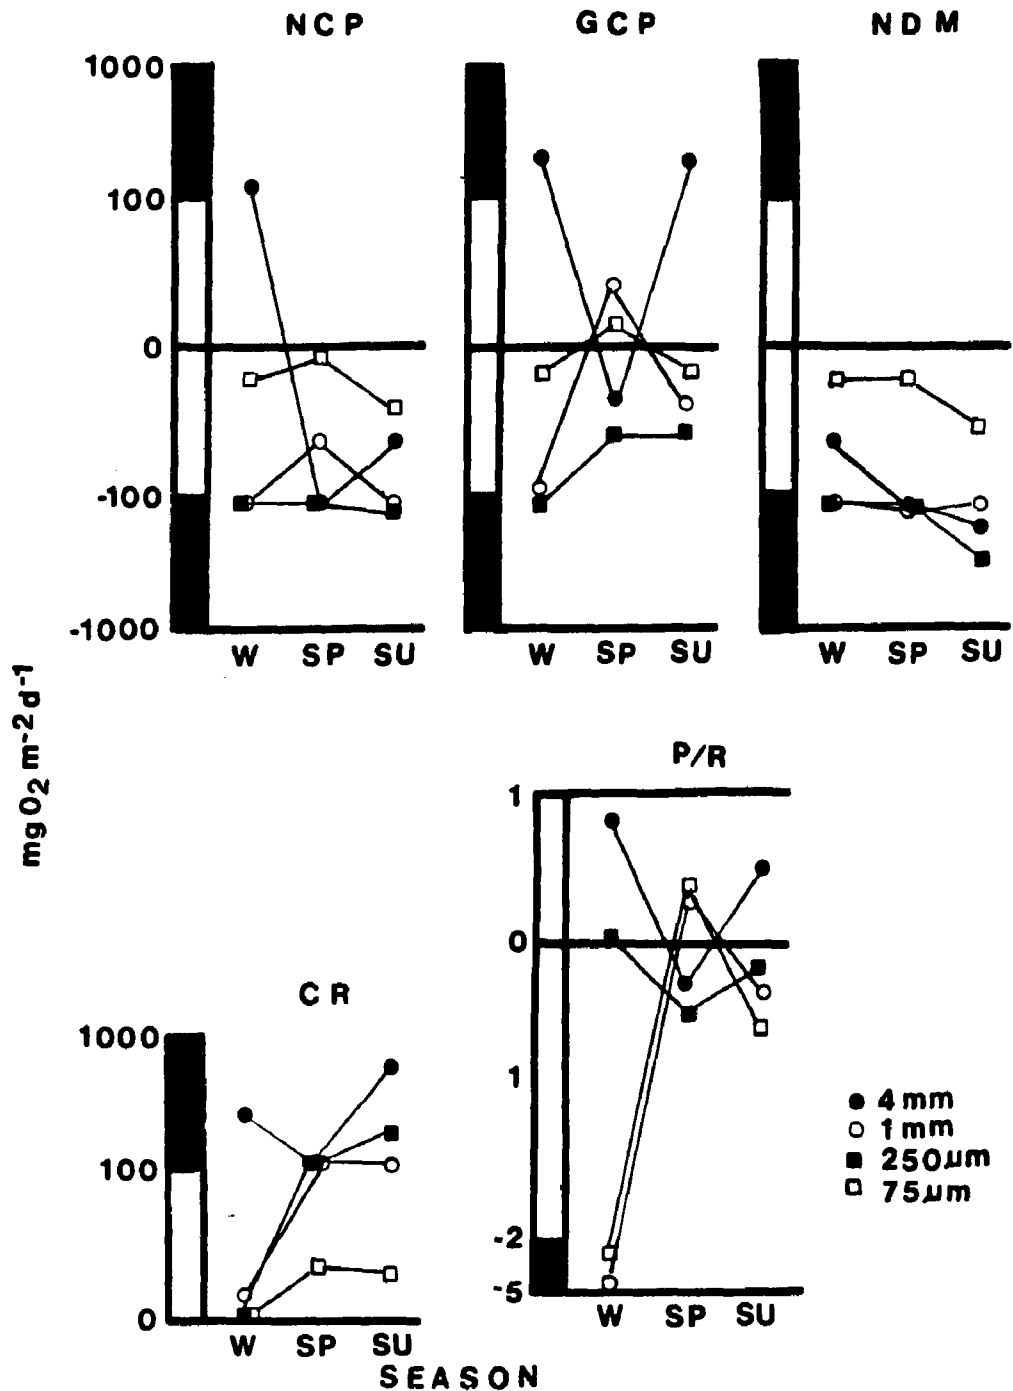

Figure 30. Estimates of particle-sized community metabolism of the epilithon of Smith riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

and NDM which mimicked in situ trends (Figures 31, 14-18). On a comparative scale the UPOM particles were lowest and 4 mm detrital particles highest in autotrophic potential. The similarity in rates of NCP and CR of the other particles indicated that after breakdown to 1 mm and finer, detrital particles had a consistent heterotrophic (probably largely bacterial) flora; the UPOM, where increased surface area to particle size was greatest, had maximized colonization and increased rates of CR. P/R ratios, indicating the heterotrophic nature of detritus in the B Avenue riffle sections, were similar in magnitude to those of Smith detritus and all were significantly less than one (Figure 31).

The primary productivity capacity of the inorganic substrates at the B Avenue riffles also depicted a dependence on allochthonous substrates (Figure 32). NDM was below zero for all particles over the sampling period. NCP was positive only for 4 mm and 250 μm particles in the spring during the diatom bloom; levels of NCP were highest for most particles during that period. As in situ, the P/R ratios were consistently less than one with the highest levels in spring; patterns of epilithon CR were also similar to in situ (Figures 32, 14-18). When comparing detrital and epilithon autochthonous contributions to riffle community metabolism at this site it was obvious that the little algal colonization which occurred did so in the epilithon community.

As on a weight basis, the small autotrophic potential demonstrated at the Upper 43rd Site in the detrital community, was due to the 0.45 μm particulate fraction in June (Figure 33). This June maximum was evident in in situ measurements of NCP, GCP, and NDM as

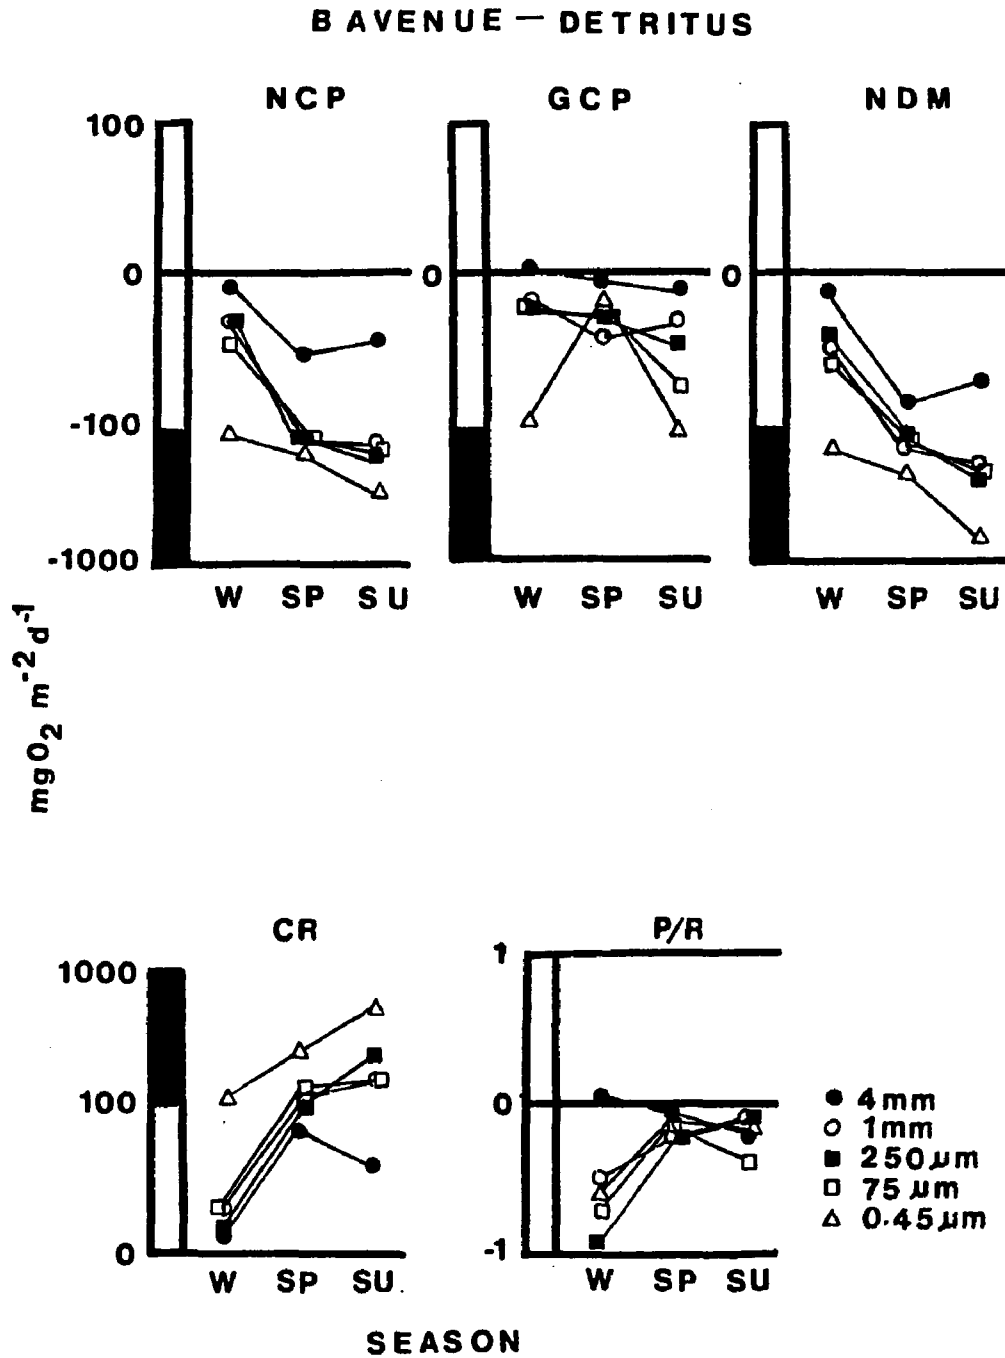

Figure 31. Estimates of particle-sized community metabolism of the detrital component of B Avenue sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

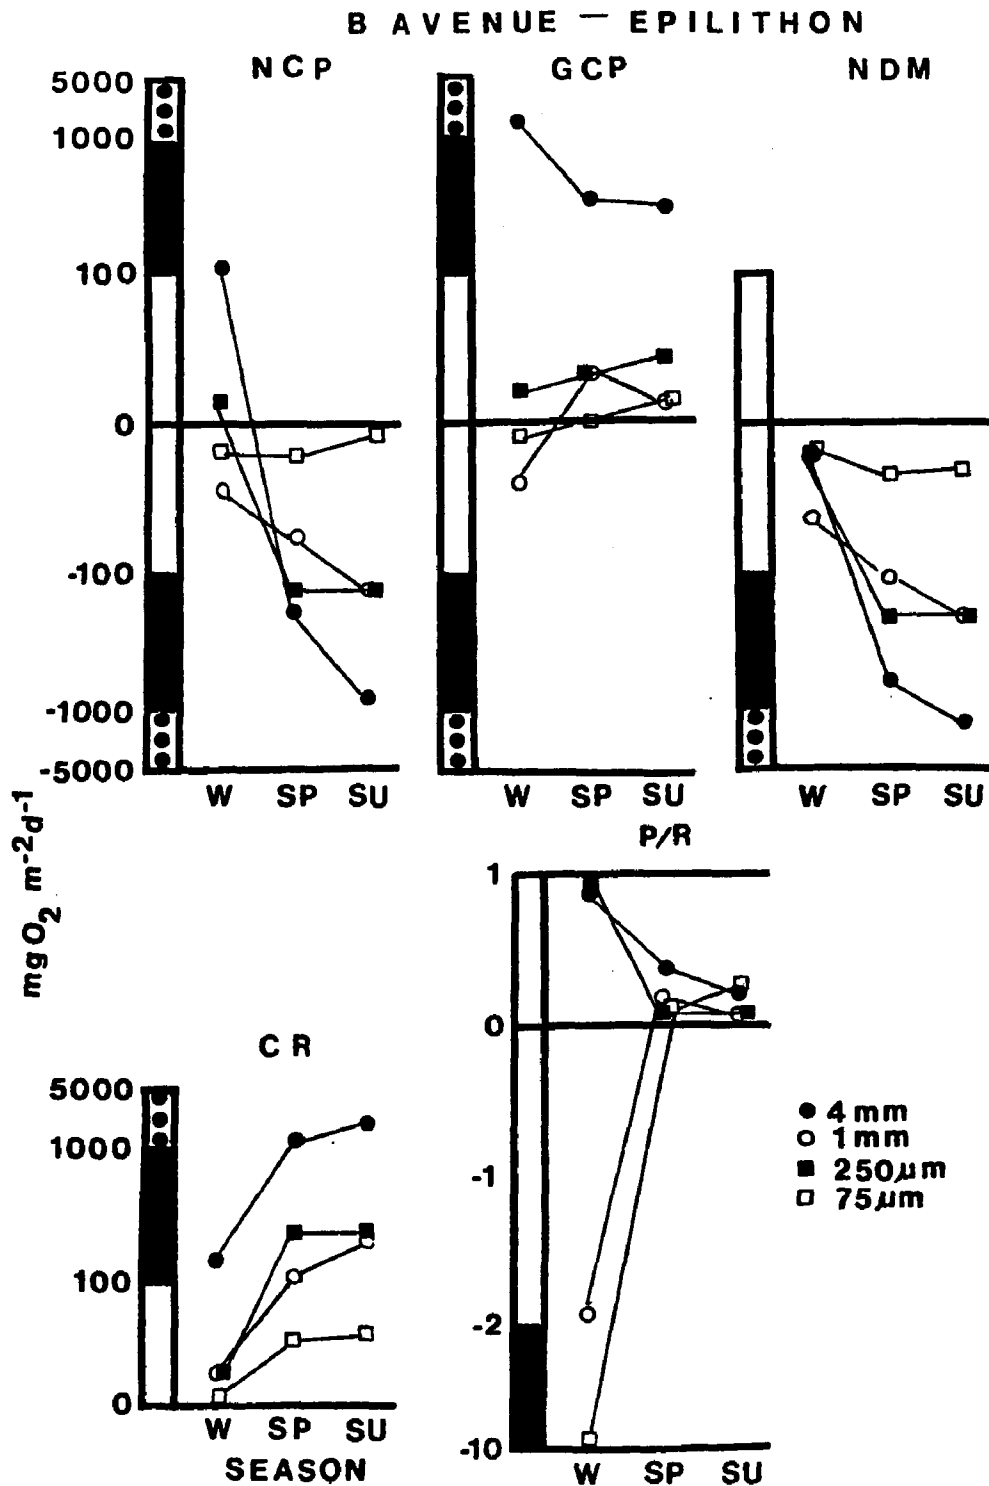

Figure 32. Estimates of particle-sized community metabolism of the epilithon of B Avenue riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

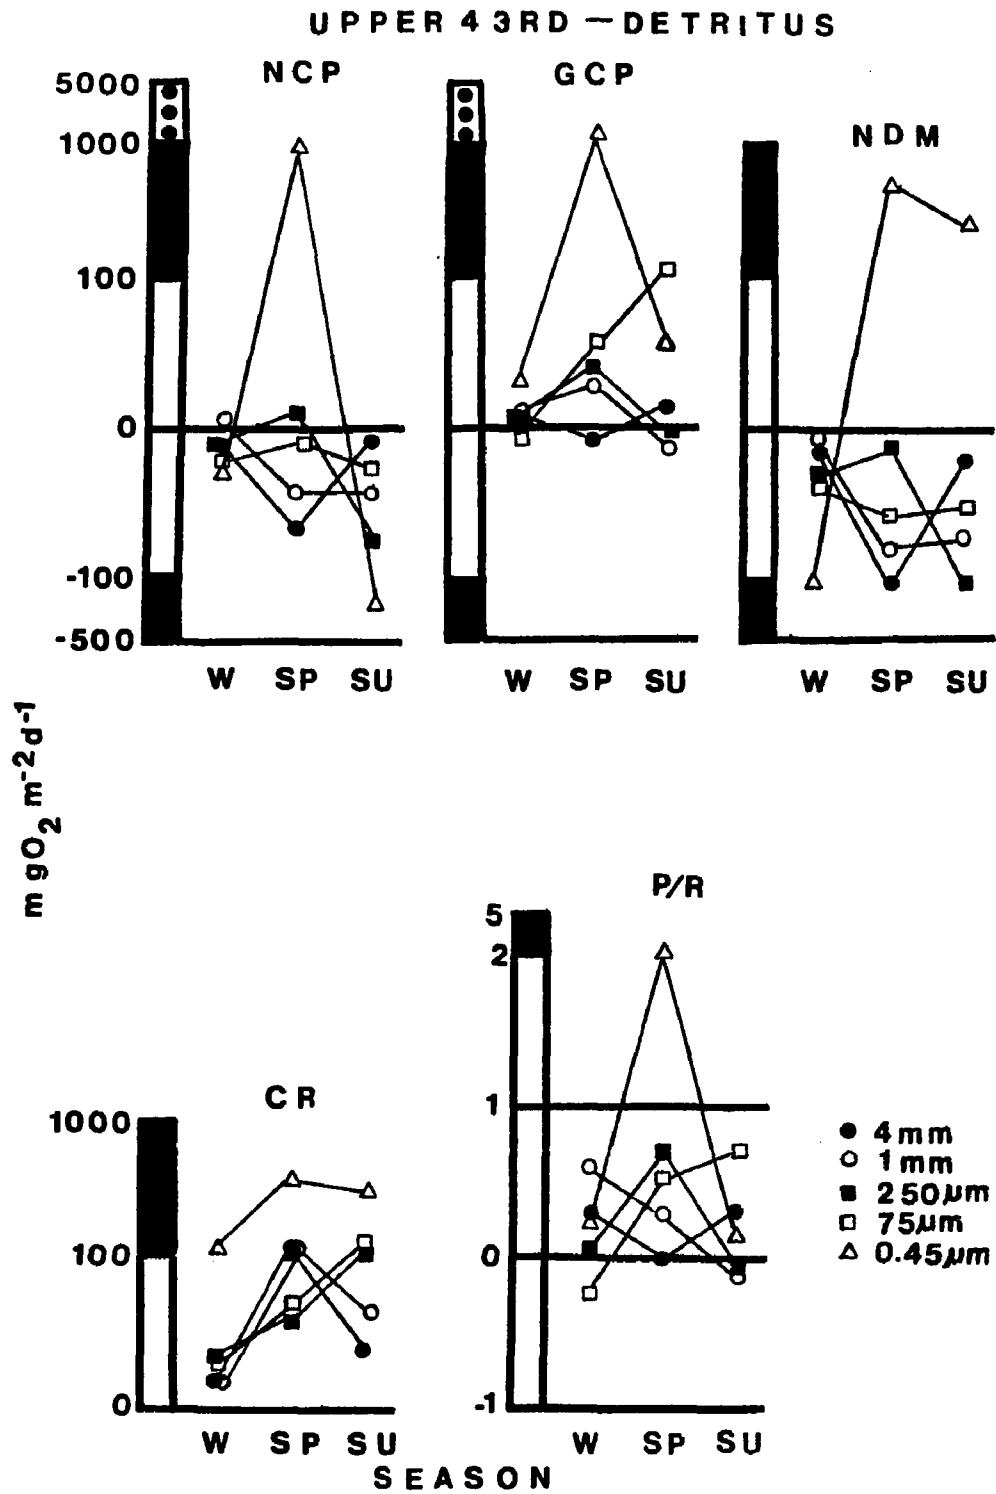

Figure 33. Estimates of particle-sized community metabolism of the detrital component of Upper 43rd riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

well (Figures 33, 14, 15, 18). Although NCP was positive only during June, GCP in the UPOM fraction was positive from February to August. During February, diatom colonization was evident on all available surfaces and could well have been a part of the FPOM pool. The June increases in the UPOM fraction as well as the 75 μm particles were related to periods of algal input. Length measurement of two common diatoms of the spring bloom: Diatoma vulgare Bory (30 to 60 μm length) and Meridon circulare (12 to 80 μm length) (Hustedt 1930) support this hypothesis. NDM in the 75 μm fraction indicated carbon was produced in excess during June and August, while the other particle sizes were generally below zero in NCP and NDM (Figure 33). GCP was positive for most particles; the 75 μm and 0.45 μm particles had the highest values. CR was highest for the UPOM with other sizes lower and similar (Figure 33). P/R ratios were generally below one, but much higher than the Smith and B Avenue values. These data suggest algal colonization and autochthonous contributions to the energy base of the Upper 43rd riffle by the detrital community.

Based on levels of particle-sized epilithon primary productivity, the Upper 43rd epilithon community had a definite algal component (Figure 34). The only similarity with detrital contributions was levels of CR (Figure 33); even maxima of productivity occurred at different times with epilithon preceding detrital, which added support to the algal input hypothesis. NDM and P/R ratios were above one indicating an autotroph dominated system in most cases. The 4 mm inorganic particles had the greatest contributions to the autochthonous organic pool of the riffle section as indicated by values of NCP, GCP, NDM, and P/R (Figure 34). High rates of CR for the larger inorganic

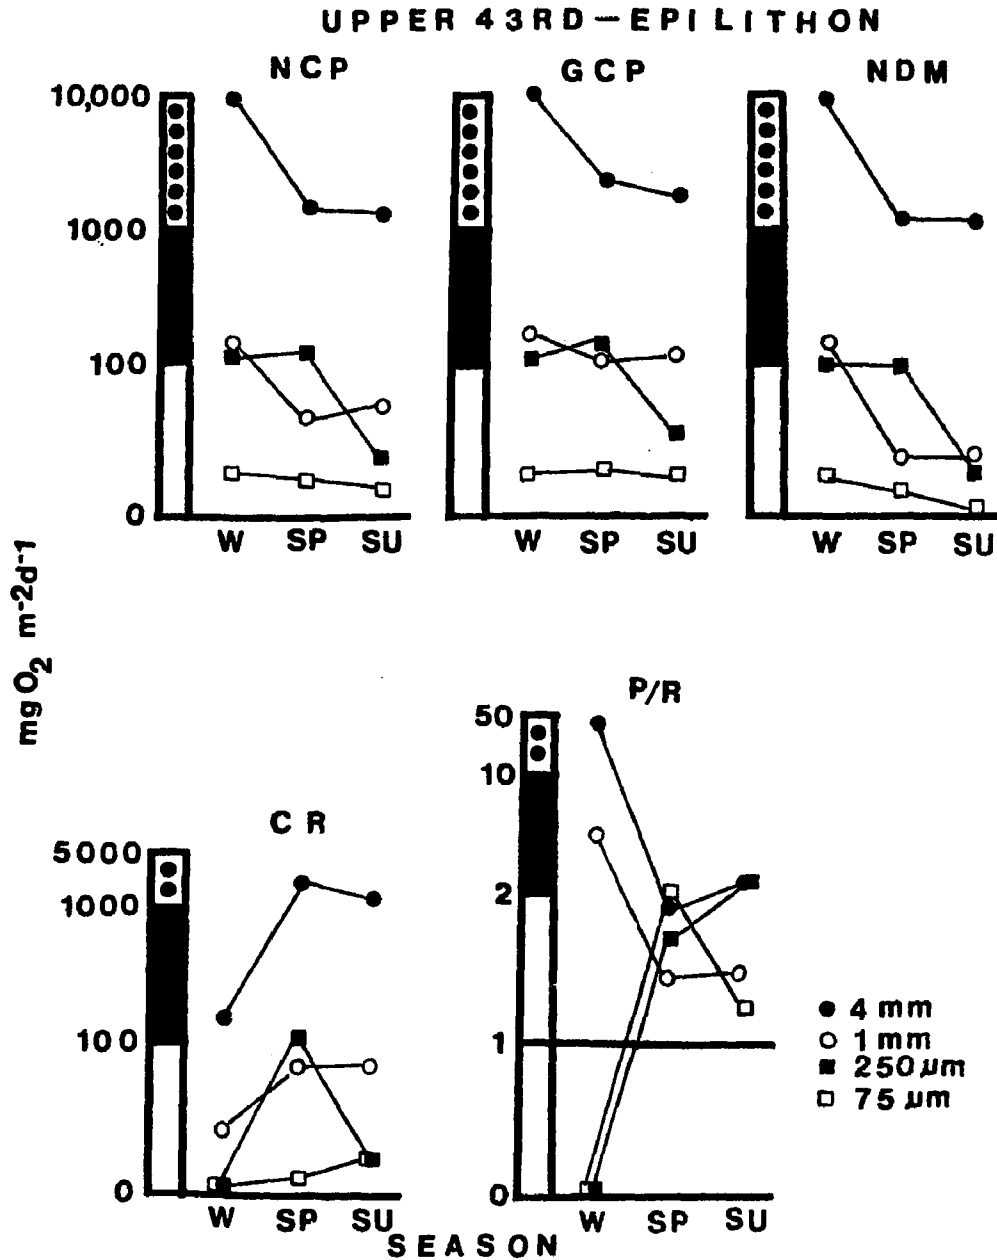

Figure 34. Estimates of particle-sized community metabolism of the epilithon of Upper 43rd riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

substrates indicated higher colonization both heterotroph and autotroph (Figure 34). The smallest sands had the least impact from all standpoints. While detrital patterns in NCP (Figure 33) did not follow in situ trends, the epilithic contributions did, which indicated a dependence on epilithon development for increased NCP.

At the Nagel Site patterns of detrital community metabolism were similar to those of Upper 43rd (Figures 33, 35). NCP values were negative and very similar for all segments, GCP was positive during the February diatom bloom for 4 and 1 mm pieces and 0.45 μm detritus in June and August (Figure 35). The summer increases were related to algal sloughing into the detrital pool. CR was also highest for this site in the UPOM with other sizes lower and similar in value. P/R ratios were all less than one and intermediate between the extreme lows of B Avenue and Smith Sites and the higher Upper 43rd values. The only trend similar to in situ measurements was for CR (Figure 35).

Particle-sized estimates of community metabolism at the Nagel site further expanded the importance of the larger stones as substrates for colonization (Figure 36). The patterns and magnitudes of parameters were similar to those of the Upper 43rd epilithon, and reflected in situ trends. This further substantiates the productivity potential of inorganic sediments within autotrophic riffles (Figures 34, 36).

Consistently below zero levels for NCP, NDM and P/R characterized the heterotrophic nature of the Kellogg Forest detritus. The 4 mm fragments had the highest percentage algae/surface area as it yielded the highest estimates of NCP and NDM with the lowest rates of CR (Figures 37). The highest CR and corresponding lowest NCP and NDM

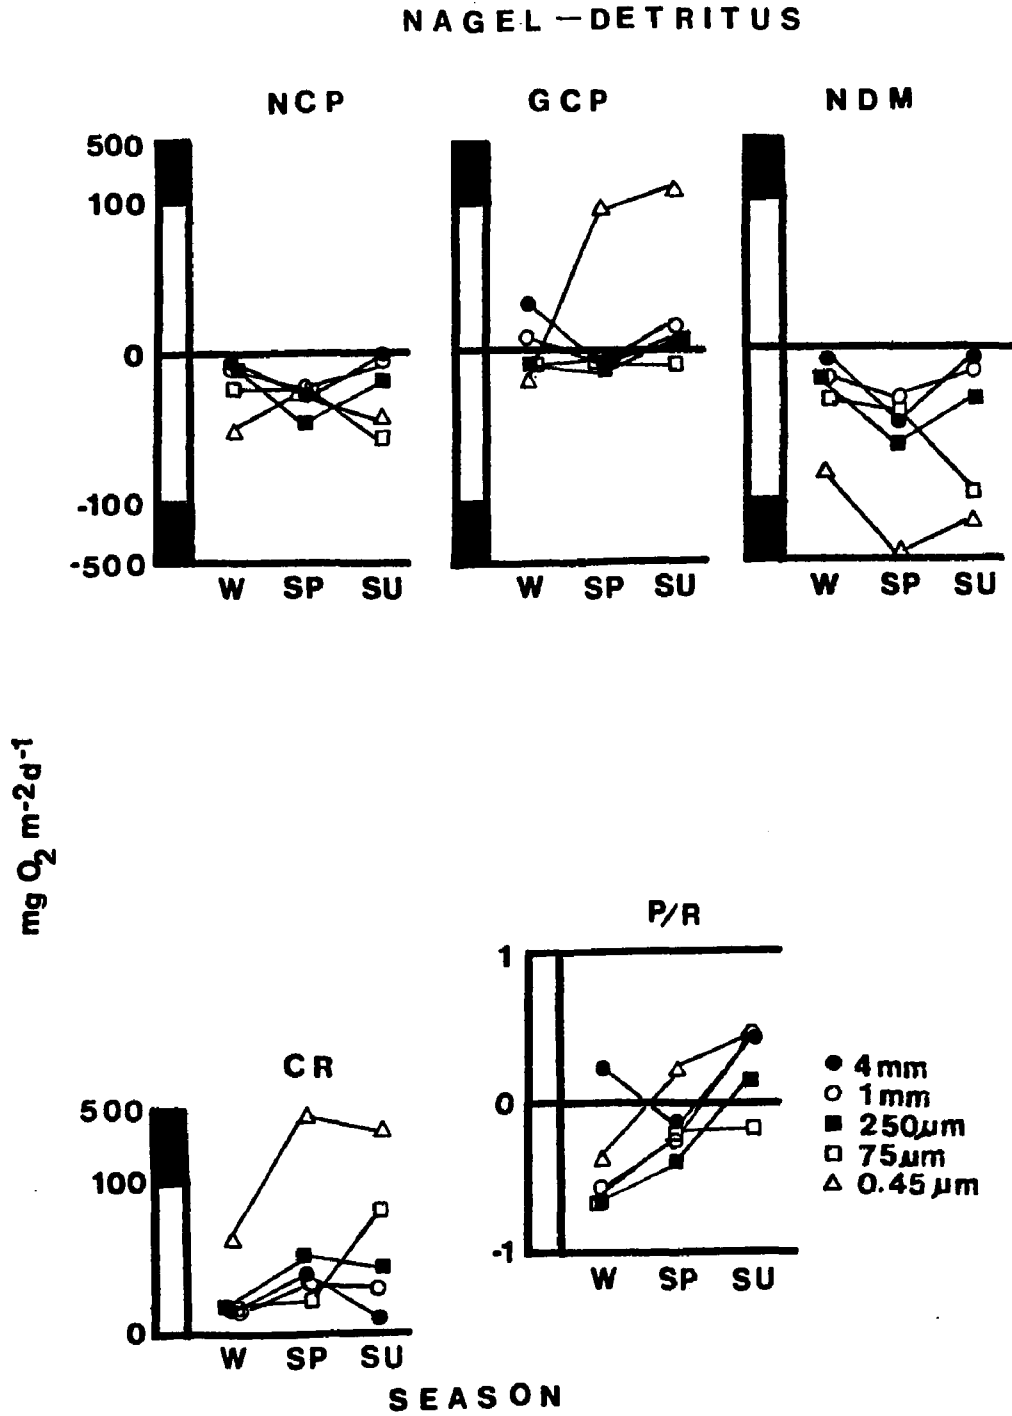

Figure 35. Estimates of particle-sized community metabolism of the detrital component of Nagel riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

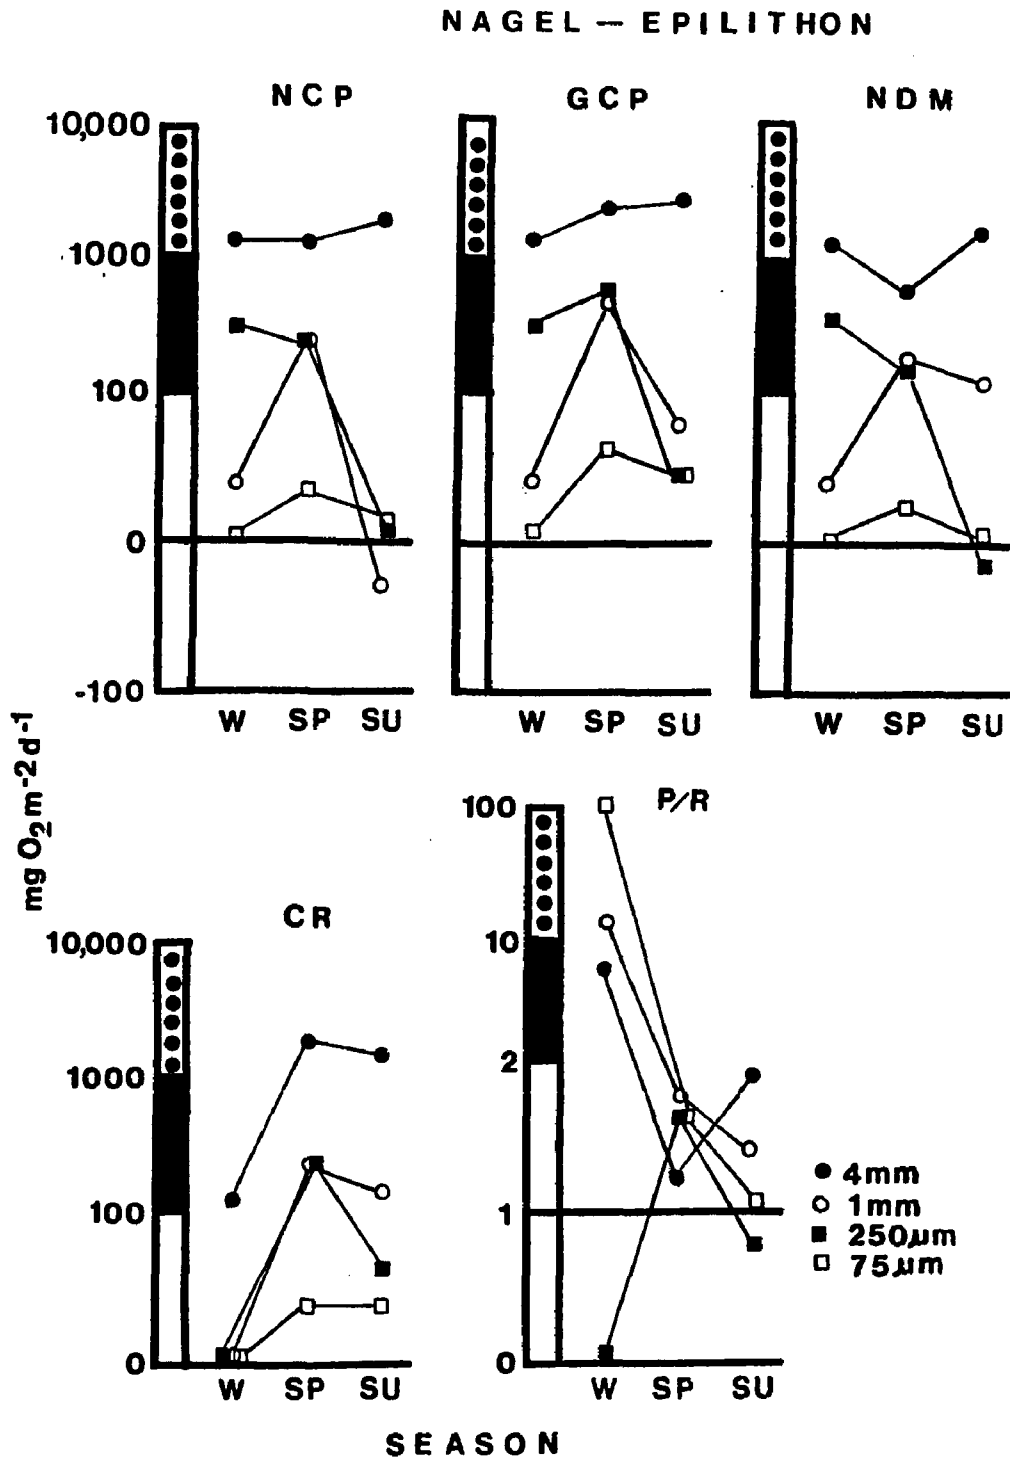

Figure 36. Estimates of particle-sized community metabolism of the epilithon of Nagel riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

were from the UPOM particles. GCP was positive for the UPOM segment which indicated potential algal inputs into this pool, yet NDM remained below zero for all segments. P/R ratios were similar to Nagel (below one) and intermediary to the extremes. The UPOM ratios were again the highest and most consistent (Figure 37). CR patterns were similar for all groups of detritus except 75 μm , which may have been increased by algal inputs, as at Upper 43rd. Illustrating the dependence of NDM on CR and in turn amounts of detritus in the sediments, estimates of detrital NDM and in situ NDM indicated similar patterns. General correspondence with in situ trends was seen only for the 0.45 μm fraction, which notes the importance of this fraction in the autotrophic-heterotrophic community balance (Figures 37, 14-18).

Autotrophic productivity of the epilithon at the Kellogg Forest was lowest during the early spring, increased in summer and decreased in late August (Figure 38). NCP and GCP values were positive for most particles over the experimental period and were similar to in situ (Figures 14, 15). CR rates followed the same pattern as NCP, GCP and in situ except 4 mm epilithon which remained high and stable (Figures 16, 38). NDM was characteristically above zero and was similar to in situ patterns (Figures 18, 38). In all cases 4 mm particles had the highest impact on overall NCP, GCP, CR, and NDM others were similar in levels of activity. The P/R ratios of 1 mm sands were consistently above one, while each of the others at some period fell below the compensation point (Figure 38). The only inorganic particles which followed in situ P/R trends were the 4 mm stones (Figures 17, 38). This site indicated a photosynthetically active community with all

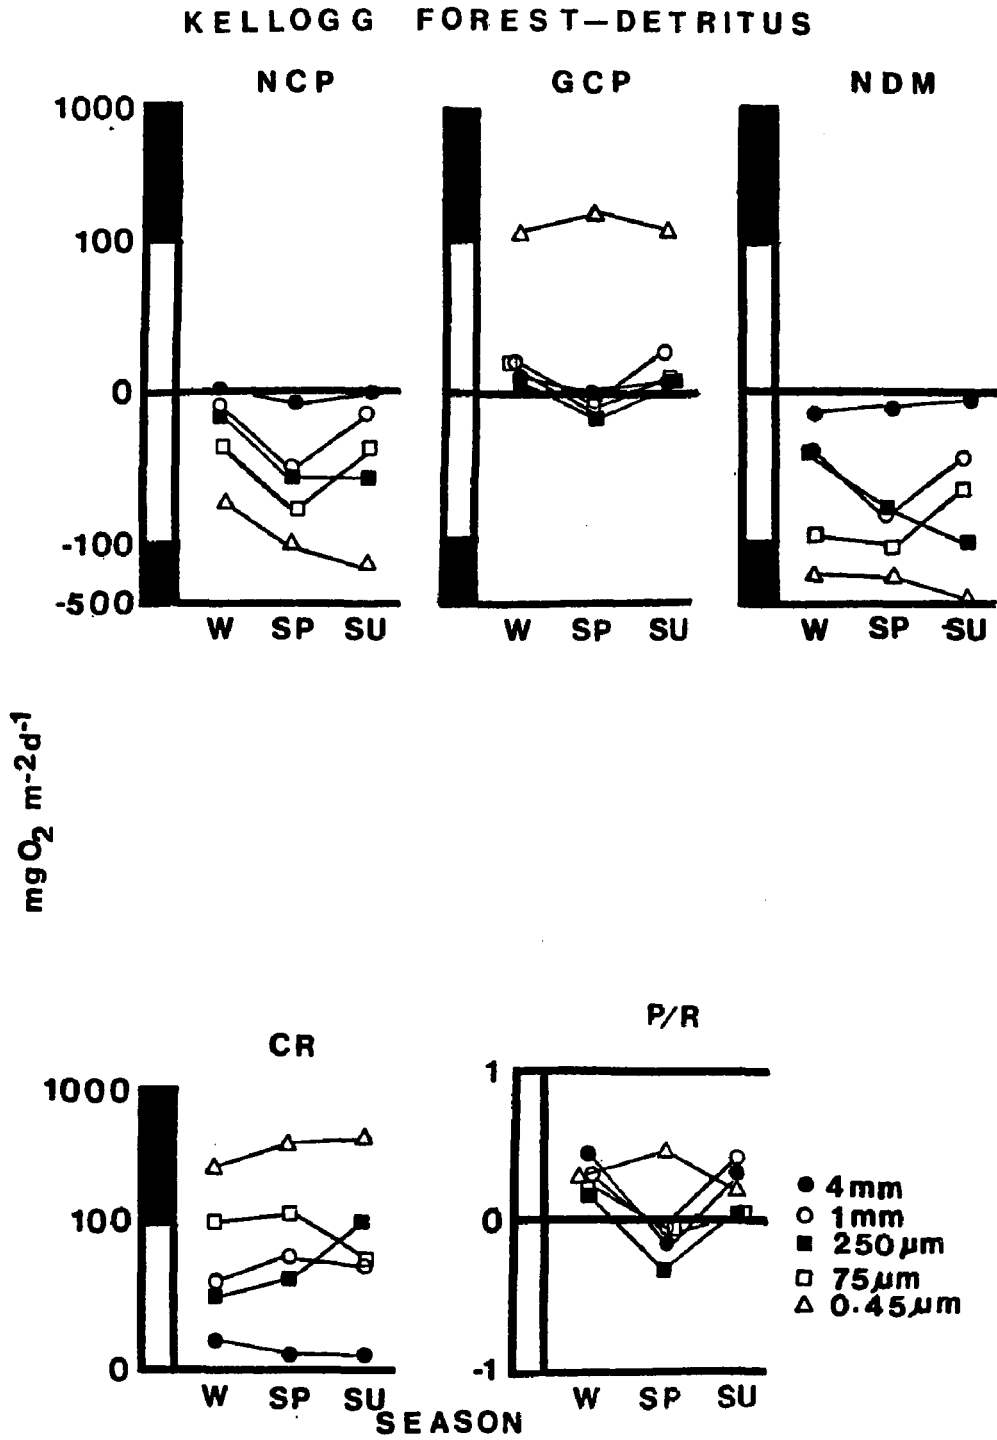

Figure 37. Estimates of particle-sized community metabolism of the detrital component of Kellogg Forest riffle sediments, Augusta Creek, Kalamazoo County, Michigan (1974-1975).

KELLOGG FOREST—EPILITHON

inorganic sediments contributing to the autotrophic potential of the riffle reach. However, the majority of colonization occurred on 4 mm and larger particles.

SYNTHESIS

Babbling brooks won't tell...
Sunlight dappling jubilantly won't tell...
Neither will the stately adjacent tree or jewelweed glistening
in a patch of sunlight bankside...
Of the complexity within. February 1982

Using a chamber method, in situ measurements of community metabolism, light, temperature, and substrate composition were monitored over a two year period in five riffle sections of Augusta Creek, Michigan. These included the first order shaded Smith and B Avenue Sites, meadow second order Upper 43rd Site, cleared third order Nagel Site, and the shaded third order section in the Kellogg Forest. During 1973-1974 daily estimates were made each month at B Avenue and Nagel Sites and daily seasonal estimates were made at the five sites during 1974-1975.

Physical and biological differences between sites were illustrated and reinforced the complexity of patterns of stream metabolism and productivity potential of woodland stream riffle sections.

Temperature

Typical temperate region seasonal patterns of temperature occurred at each site with maximum temperatures during the summer and minima during the winter. Maxima at the sites ranged from 19.9 C at

Smith and B Avenue Sites to 24.8 at Upper 43rd Site. Average daily temperatures ranged from 0.4 C at Upper 43rd in winter to 22.6 C at Nagel in August. First order sites were lowest, open sites highest, and shaded Kellogg Forest intermediary. Average daily temperatures plateaued at maximum temperatures in June and remained high until September at both shaded and open sections.

Greatest daily temperature fluctuations ranged from 5.8 to 10.5 C with the highest fluctuations occurring at first order sites during spring and fall. Indicating the importance of canopy in maintaining cooler conditions, the largest annual averages were for the open sites.

Light

Average daily light measured at the riffle sections was highest (90,213 lux) at Upper 43rd in May and lowest (2,391 lux) at B Avenue in January, while averages over the study period ranged from 12,054 lux at Smith to 43,622 lux at Upper 43rd. First order sites were lowest, open sites highest and Kellogg Forest intermediary.

Smith and B Avenue sites received only 45% of the illumination of the shaded third order Kellogg Forest and only approximately 30% of the open sites. Open sites received approximately 140% of the shaded third order sites and Kellogg Forest approximately 66% of the light at open sites. Open sites displayed light patterns typical of temperate regions with spring-summer maxima and winter minima. June through September (leaf-out) light reductions were evident at Smith and B Avenue sites as were increases in light after canopy abscission. Even though complex dappled light patterns were evident at the Kellogg

Forest site, significant light inputs were evident. On a comparative scale lower light values were evident due to shading at these three sites even during winter.

Ranking by average light input Smith was lowest followed by B Avenue, Kellogg Forest, Nagel, and Upper 43rd. Thus, light trends indicated the diversity of light patterns natural and man made along a continuum.

Community Metabolism

GCP values, ranging from 0.09 to $5.35 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at Smith Site in winter and Nagel Site in August, respectively, varied seasonally and between sites over the annual period. Highest values were during the spring at naturally shaded sites and summer at open sites. On an average the lowest levels were at Smith followed by B Avenue, which had a wider channel and approximately two times the GCP of Smith; Kellogg Forest; Upper 43rd; and Nagel. Levels of GCP from the first order sites were lower than reported literature values. Open sites had approximately 13% higher GCP than the first order reaches. Clearing shifted the autotrophic capacity to values typical or larger rivers.

NCP values followed the seasonal trends displayed by GCP and ranged from $-0.25 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at Smith during the fall to $4.03 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ at Nagel Site in August. The low value, during the fall, may have been the effect of leaf inputs into the shaded Smith reach and the maximum value correlated with luxuriant algal development at Nagel Site. Indicating heterotrophic conditions and a dependence on allochthonous or stored organic matter, negative NCP values were

consistent at the first order sites. Open sites and the Kellogg Forest Site indicated positive NCP values, thus, autotrophic bases. Sites ranked by average NCP were identical to GCP trends with the effects of clearing obvious from comparison of Kellogg Forest and Nagel Sites. Light saturated NCP occurred within the range of 15,000 to 24,000 lux at sites of Augusta Creek and combined sites indicated a saturation level of approximately 20,000 lux. Smith exhibited no saturation plateau, but light values rarely exceeded 20,000 lux at this site. Temperature did not affect light saturation thresholds. No photoinhibition was indicated at either autotrophic or heterotrophic sites.

Rates of CR varied significantly between shaded and open sites. The range of values was $0.24 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ during January at B Avenue to $3.67 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ during July at Nagel Site. On an average basis B Avenue and Smith were similar and low, Kellogg Forest was intermediate, and Nagel and Upper 43rd were similar and higher in values. Kellogg Forest rates approximated rates of the heterotrophic sites with the only significant deviation occurring during periods of leaf-out when CR levels increased at Kellogg Forest corresponding with increased epilithon development. Seasonal patterns were similar at most sites with lowest rates during the winter and highest values during spring or summer. ~~An inverse relationship was noted~~ between CR and NCP at heterotrophic sites. CR as a percent of GCP varied from 445% at Smith to 55% at Kellogg Forest. Autotrophic sites averaged 65% while heterotrophic sites averaged 322%, which indicated a considerable deficit of organic carbon from autochthonous organisms at B Avenue and Smith Sites. Effects of clearing at Nagel compared to

the shaded Kellogg Forest indicated increased CR with greater epilithon development at the Nagel Site.

P/R ratios at the five sites indicated consistent consuming modes at B Avenue and Smith and producing modes at the open and Kellogg Forest Sites over the year. Upper 43rd, closest to P/R = 1, indicated little excess autochthonous production for export or storage. Lowest P/R ratios were obtained on a snowy overcast day at B Avenue (-0.017) and highest (2.5) at the Nagel Site in August. Average P/R ratios ranked sites in increasing order: Smith, B Avenue, Upper 43rd, Nagel, Kellogg Forest. A trend of increasing P/R with increased stream order was noted. The high levels at Kellogg Forest were attributed to lesser development of epilithon with increased light availability maximizing efficiency and, thus, indicated the autotrophic potential of shaded third order reaches. Highest ratios corresponded with trends of GCP and NCP with spring peaks at all sites and maximum in summer at the cleared Nagel site. Low values were during the winter at all sites. The low ratios obtained at Smith and B Avenue were similar to those reported from turbid or polluted systems and the open sites approximated values of larger rivers. Average P/R ratios from monthly estimates at B Avenue and Nagel Sites were not significantly different from averages obtained on a seasonal basis, which indicated seasonal monitoring was sufficient to characterize the autotrophic-heterotrophic capacity of a riffle.

NDM values were similar to NCP and P/R trends, but were lower in magnitude. Values ranged from $-0.72 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ in fall at Smith to $2.68 \text{ g O}_2 \text{ m}^{-2}\text{d}^{-1}$ in August for Nagel. Lowest NDM values were in the winter, and at B Avenue and Smith consistent negative values indicated

dependence on allochthonous POM since no pool of autochthonous carbon was present. Lowest values, during fall at Smith, indicated the effects of increased CR concomitant with CPOM inputs. Open sites and the Kellogg Forest Site were autotrophic in nature as indicated by positive NDM values with Nagel and Kellogg Forest capable of storage or export of autochthonous carbon and Upper 43rd Site was basically self-supporting with periods of potential dependence on the slight storage capacity or POM or allochthonous carbon corresponding to periods of low NCP and NDM. Average NDM was lowest at Smith followed by B Avenue, Upper 43rd, Kellogg Forest and Nagel, which indicated that even though the highest P/R ratios were at Kellogg Forest, actual carbon production was greatest at Nagel and that the shaded Kellogg Forest produced more excess carbon than the open Upper 43rd Site.

Detrital standing crop analyses indicated stable levels of detritus at each site with all but the extremes (Smith high and Upper 43rd low) similar in amounts. Standing crops ranged from 592 to 145 g m⁻². No consistent seasonal trends were found between sites. First order sites had greater variance in standing crop levels while open and Kellogg Forest Sites remained stable. Average detrital standing crops for sites ranked in decreasing order were Smith, Nagel, B Avenue, Kellogg Forest and Upper 43rd. The high levels of detritus at Nagel were attributed to inputs of filamentous algae and aquatic macrophytes as were the high average CPOM/FPOM ratios. This ratio varied from 0.06 during summer at Kellogg Forest to 0.68 at Nagel Site in winter with an inverse relationship between CPOM/FPOM and P/R. On an average basis sites ranked in CPOM/FPOM ratio in increasing order were Kellogg Forest, Smith, Upper 43rd, B Avenue, Nagel.

Patterns of community metabolism expressed on a g^{-1} AFDW detritus basis did not reflect levels of standing crop, as values varied in activity differently from detrital ranking. CR maxima were highest during the fall in contrast to spring and summer on an area basis, which was attributed to a more labile (algal) input to the riffles at that time. First order sites were more stable in rates of community metabolism per gram detritus over the year which indicated a bacterial metabolic base. NDM values, indicating a dynamic equilibrium with each community of either an autotrophic or heterotrophic energy base, were consistent at each site. Since standing crop levels were not significantly different at most sites, little change in community metabolism trends were expected expressed on a weight basis.

The concept of use of epilithon development (AFDW) as a mechanism to monitor autotrophic-heterotrophic capacities of riffle reaches was introduced. Values, obtained by ashing inorganic substrates including detrital and algal biomass, ranged from $1480 g m^{-2}$ at Smith during spring to $5030 g m^{-2}$ at Nagel during the same period. Obvious visual differences as well as biomass values varied with site and followed patterns of NCP and GCP in the riffles. Sites ranked Smith, B Avenue, Kellogg Forest, Nagel and Upper 43rd in average epilithon development. Seasonal variation was greatest at the open sites (C.V.%), while first order heterotrophic sites remained low and stable indicative of a bacterial base. Kellogg Forest was also stable, but had higher levels of epilithon development than the first order riffles. Even at Smith Site epilithon was a significant component of the total organic standing crop. Based on the low rates of NCP and GCP at this site it was detrital based epilithon, while open and shaded third order sites

had algal based epilithon. Peaks of epilithon occurred in fall at Smith during CPOM inputs and at open sites during spring and fall, which correlated with the diatom blooms. Major changes occurred on the larger substrates. Detritus averaged 12% of the TPOM; the range was 18% at Smith Site to 7.5% at Upper 43rd Site. Differences existed between autotrophic and heterotrophic sites. Use of the E/D ratio for characterization of riffle reaches was proposed. Average E/D ranged from 4.5 at Smith to 14.8 at Upper 43rd with increased importance of the epilithon (Algal and detrital) at the open sites. E/D had a direct relationship with NCP, GCP, and P/R for sites of Augusta Creek. However, higher values of E/D were obtained on an extremely heterotrophic riffle reach of a branch of the Yellowstone River, Montana, which indicates E/D indicative of the epilithon to non-attached detritus contribution to riffle energy bases, but NCP, P/R, and NDM estimates indicate the detrital-algal (autotrophic-heterotrophic) contributions of the components. E/D ratios used with P/R and NDM were of value in characterization of riffle sections.

Regression Analyses

Regression analyses involving the independent variables stream order light, temperature, detritus AFDW, epilithon AFDW, and total particulate organic matter and the dependent variables NCP, GCP, CR, and NDM indicated stream order to be the most highly correlated parameter with all dependent variables ($R = 0.52$ to 0.74 ; $F = 37$ to 122). Therefore, the importance of geomorphology was evident from a functional standpoint.

Light was also highly significant ($P < 0.01$) in cases of NCP,

GCP, and NDM based on average values ($R = 0.52$ to 0.57 ; $F = 36$ to 46) and on an individual basis ($R = 0.6$; $F = 1090$). In multiple regression with temperature $R = 0.597$ for light while the temperature R value was only 0.005 . Compared with other variable independent variables monitored, light was the most important factor influencing NCP, GCP and NDM. On a site basis positive relationships were evident with light, but not as highly correlated. Significance increased with increasing order which indicated the increasing importance of light on open sites.

Temperature had a positive significant relationship with all average parameters with CR highest ($R = 0.65$; $F = 70$) and NCP lowest ($R = 0.33$; $F = 12$). As CR varied little over the annual period in headwater first order streams, the relationship was less clear which indicated a stable community in dynamic equilibrium. Temperature was most strikingly related to NCP at open sites; on a site basis the most significant relationships were with temperature.

The detrital content of the sediments had little effect on averaged or site basis community metabolism. Average NCP, and NDM were most highly correlated ($R = 0.12$; $F = 1.3$ and $R = 0.12$; $F = 1.4$), but not highly significant ($P = 0.26, 0.24$).

Epilithon development was highly significant with all averaged dependent variables with NCP correlating most closely ($R = 0.42$; $F = 17.6$). Although on a site basis significance levels decreased, a much stronger relationship existed for epilithon and rates of community metabolism than detritus.

Total AFDW correlations were slightly reduced by addition of detritus in most cases, but were close to the values for epilithon.

Particle Sized Community Metabolism

The impact of various particle sizes (4 mm, 1 mm, 250 μm , 75 μm , 0.45 μm) for detritus and epilithon (Excepting 0.45 μm) was determined. Activity g^{-1}AFDW and areal estimates based on standing crop data were compared to examine the size activity and ecological impact respectively. All estimates were higher than in situ which indicated the inadequacy of short term estimates at light saturation levels for estimation of community metabolism, the possibility of disturbing particles in separation, or the potential of maximizing surface in Gilson vessels versus the packed condition typical of in situ conditions. However, relative comparisons may be made between particle sizes and sites.

Absolute rates of detrital NCP ranged from -318 to 1688 $\mu\text{lO}_1 \text{g}^{-2}\text{h}^{-1}$ for 0.45 μm detritus at B Avenue and Upper 43rd respectively. At all sites most particle sizes were similar and negative in NCP except the 0.45 μm fraction, which was generally most negative in value. Average rates at Smith and B Avenue were considerably lower than the autotrophic sites and average particle size rates were highest for 0.45 μm followed by 1 mm, 250 μm , 4 mm, and 75 μm .

CR of detritus particles ranged from 15 to 739 $\mu\text{lO}_2 \text{g}^{-1}\text{h}^{-1}$ for 4 mm particles at Nagel in March and 0.45 μm detritus at Upper 43rd in June. On an average 4 and 1 mm particles had lowest CR and 0.45 μm particles highest CR, but particles were mainly similar except for high rates in the 0.45 μm fraction. On a site basis 0.45 μm was highest at all sites, but no inverse trend was indicated in CR and particle size. Sizes ranked from lowest to highest CR were Upper

43rd, Kellogg Forest, B Avenue, Smith and Nagel. Detritus CR was higher for all fractions than epilithon on a weight basis. Inorganic sediment CR average 70% the rates of detritus with 4 and 1 mm particles about 35% their detrital counterparts and 250 and 75 μm were nearly equal; a similar, probably bacterial dominated flora, developed on both inorganic and organic substrates.

On epilithon, CR ranged from undetectable for 250 μm sizes at Smith, Nagel, and Upper 43rd to $215 \mu\text{lO}_2 \text{ g}^{-1}\text{h}^{-1}$ for 75 μm sands in June at the Kellogg Forest Site. Rates exhibited an inverse relationship with particle size. Sites ranked Kellogg Forest, Upper 43rd, B Avenue = Nagel, and Smith in increasing levels of CR. Epilithon CR values were similar at B Avenue and Nagel Sites, but a different floral composition was evident based on levels of primary productivity; B Avenue was bacterial dominated and Nagel algal dominated.

Epilithon NCP had a greater range than detritus (-321 to +2174 $\mu\text{lO}_2 \text{ g}^{-1}\text{h}^{-1}$) for 75 μm Smith sands to 4 mm Kellogg Forest gravel. Averages for particle-sizes indicated 1 mm to be lowest in NCP and 4 mm highest. All inorganic sediment sizes were colonized by autotrophs at Upper 43rd and the majority at Nagel and Kellogg Forest on an annual basis. Heterotrophic sites had little algal colonization indicated, but 4 and 1 mm fractions exhibited weak autotrophic potentials. Sites ranked Smith, B Avenue, Nagel, Upper 43rd, and Kellogg Forest in average increasing NCP.

Since particle-size distribution affects total sediment community metabolism, estimates were calculated on an areal basis. Detrital NCP was generally highest on 4 mm particles with a direct inverse relationship evident between NCP and particle size. On an average

site basis $0.45 \mu\text{m}$ detritus was highest in NCP with no trend following for other particle-sizes. CR averages had an inverse relationship between particle size and CR, which was not evident on a weight basis.

Epilithon NCP and CR on an areal basis were dominated by 4 mm stones followed by $250 \mu\text{m}$, 1 mm, and $75 \mu\text{m}$ size. GCP, calculated only on an areal basis, indicated the detrital segment to be in a consuming mode with positive values only for 4 mm detritus at B Avenue in the fall, $0.45 \mu\text{m}$ seasonally, and all segments periodically at Upper 43rd, Nagel and Kellogg Forest. NDM remained below zero for all particle sizes except $0.45 \mu\text{m}$ in spring and summer at the Kellogg Forest, which indicated algal inputs to the FPOM pool. P/R ratios were all below one except for $0.45 \mu\text{m}$ particles in spring at Upper 43rd.

Epilithon patterns were more complex with GCP from 4 mm, 1 mm, and $75 \mu\text{m}$ inorganic sediments contributing periodically at Smith; 4 mm annually and all other periodically at B Avenue; 4 and 1 mm and $250 \mu\text{m}$ sediments generally contributing annually at Upper 43rd; all sizes positive annually at Nagel; and Kellogg Forest had all except $75 \mu\text{m}$ sizes in a contributing mode annually. NDM was annually below zero for all particles at Smith and B Avenue and above for the majority of particles at the autotrophic sites. P/R ratios were below one for all sizes at heterotrophic sites and above one for most particles at autotrophic sites with exceptions in the smaller particle sizes.

Overall, $0.45 \mu\text{m}$ detritus had the greatest CR and all sizes illustrated little productive capacity on a weight basis, while inorganic sediments had greatest NCP on larger substrates and CR in the smaller fractions. On an areal basis productivity was highest on

larger fractions of both detritus and inorganic sediments; the majority of NCP occurred on the inorganics. CR was highest on smaller detritus and larger inorganics.

Sites

Smith, a first order site, was heterotrophic in nature, detrital based, dependent mainly on epilithic detritus for organic support with little autochthonous production. What little GCP took place did so on the larger substrates. P/R ratios were less than one, NDM below zero and E/D ratios constant and low (3.7 to 4.8), which indicated the impact of allochthonous inputs to the riffle community.

B Avenue, a slightly larger first order reach, was also heterotrophic dependent on allochthonous detritus trapped in the epilithon, but greater autochthonous activity was evident, which was at times contributing to the community support. Based on NDM and P/R ratios not enough NCP occurred for the riffle to be self-supporting. E/D ratios, averaging 7.9, and ranging from 3.5 to 16.5 indicated greater variability and changes in the epilithon flora compared to Smith Site and illustrated the periodic productive potential of the site.

Upper 43rd, an open second order meadow reach, was annually self-supporting, thus, considered an autotrophic site. Indicating the autotrophic dominance in the epilithon community, P/R ratios were near one and NDM was consistently positive. Epilithon development was high at this site as was CR which continually mediated P/R and NDM. E/D ratios were highest at this site averaging 14.8, which emphasized the importance of the epilithic community to riffle sections. Storage was

indicated at this site in the FPOM pool as high rates of NCP occurred as well as increased CR during summer and fall. High rates of NCP at Upper 43rd indicated the effects of lack of canopy at a second order site.

The open third order Nagel Site illustrated the effects of clearing on rates of third order riffle NCP as rates approximated those of larger rivers and were significantly higher than the shaded Kellogg Forest Site.

P/R and NDM indicated a producing mode to be characteristic of both sites, but at Nagel higher epilithon development occurred and subsequently increased CR, while autotrophic colonization was greater as indicated by increased rates of NCP. Indicating continued autochthonous support P/R ratios were well above one over annual periods and E/D ratios were similar to Upper 43rd at Nagel ($\bar{x} = 12$) and intermediary at Kellogg Forest ($\bar{x} = 9.5$).

The shaded Kellogg Forest third order riffle was also autotrophic in nature, lesser in productivity than the open site, but also lesser in CR and epilithon development. This riffle section was self-supporting on an annual basis as indicated by the P/R ratios greater than one and positive NDM. E/D ratios ranging from 4.6 to 15.8 indicated the diverse base of this riffle.

The autotrophic-heterotrophic balance in riffle sections was dependent on the epilithon component both in development, which was mediated by light availability, and composition which would also be affected by light, and on a species level temperature dictated.

APPENDIX E

N = number of values considered
R = multiple correlation coefficient
S.E.= standard error of regression
F ratio= test of significance for regression
 <1 no significance
 >1 significant, higher more so

M^2_{Reg} = mean² of deviation due to regression
 M^2_{Res} = mean² of deviation of residuals

P= level of significance (P=0.05 significant)

Table E - 1. Regression parameters for average NCP, CR, GCP and NDM versus various independent variables from data collected in Augusta Creek, Michigan riffle sections.

| Dependent Variable | Independent Variable | N | R | S.E. | M ² Reg | M ² Res | F Ratio | P |

APPENDIX F

Figure F - 1. Net community productivity at various light intensities for combined sites of Augusta Creek, Michigan (1973-1975).

Figure F - 2. Net community productivity at various light intensities for Smith site, Augusta Creek, Michigan (1975 - 1975).

Figure F - 3. Net community productivity at various light intensities for B Avenue site, Augusta Creek, Michigan (1973 - 1975).

Figure F - 4. Net community productivity at various light intensities for Upper 43rd site, Augusta Creek, Michigan (1974 - 1975).

Figure F - 5. Net community productivity at various light intensities for Nagel site, Augusta Creek, Michigan (1973 - 1975).

Figure F - 6. Net community productivity at various light intensities for Kellogg Forest site, Augusta Creek, Michigan (1974 - 1975).

Figure F - 7. Net community productivity within the 0 - 5 C temperature range for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure F - 8. Net community productivity within the 5 - 10 C temperature range for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure F - 9. Net community productivity within the 10 - 15 C temperature range for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure F - 10. Net community productivity within the 15 - 20C temperature range for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure F - 11. Net community productivity within the 20 - 25 C temperature range for combined sites of Augusta Creek, Michigan (1973 - 1975).

APPENDIX G

Figure G - 1. Rates of community respiration at various temperatures for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure G - 2. Rates of community respiration at various temperatures for Smith site, Augusta Creek, Michigan (1974 - 1975).

Figure G - 3. Rates of community respiration at various temperatures for B Avenue site, Augusta Creek, Michigan (1973 - 1975).

Figure G - 4. Rates of community respiration at various temperatures for Upper 43rd site, Augusta Creek, Michigan (1974 - 1975).

Figure G - 5. Rates of community respiration at various temperatures for Nagel site, Augusta Creek, Michigan (1973 - 1975).

Figure G - 6. Rates of community respiration at various temperatures for Kellogg Forest site, Augusta Creek, Michigan (1973 - 1975).

Table G - 7. Net community productivity at various temperatures for combined sites of Augusta Creek, Michigan (1973 - 1975).

Figure G - 8. Net community productivity at various temperatures for Smith site of Augusta Creek, Michigan (1974 - 1975).

Figure G - 9. Net community productivity at various temperatures for B Avenue site of Augusta Creek, Michigan (1973 - 1975).

Figure G - 10. Net community productivity at various temperatures for Upper 43rd site of Augusta Creek, Michigan (1974 - 1975).

Figure G - 11. Net community productivity at various temperatures for Nagel site of Augusta Creek, Michigan (1973 - 1975).

Figure G -12. Net community productivity at various temperatures for Kellogg Forest site of Augusta Creek, Michigan (1974 - 1975).

APPENDIX H

NCP = NET COMMUNITY PRODUCTIVITY

GCP = GROSS COMMUNITY PRODUCTIVITY

CR = COMMUNITY RESPIRATION

NDM = NET DAILY METABOLISM

Table H - 1. Estimates of mean hourly rates of community metabolism based on Gilson Respirometry from five riffle sites of Augusta Creek, Michigan.
