#### ACKNOWLEDGEMENTS

The writer expresses his sincere gratitude to Dr. Ray L. Cook for his suggestions and criticisms in the selecting and carrying out of this study. Thanks are also given to Dr. Lloyd M. Turk for reading and criticizing the manuscript and to Dr. W. D. Baten for assistance in the statistical analyses.

## INTRODUCTION

During the past century various methods of improving the fertility of crop-growing soils have been developed. Their relative importance of the early investigations, one should give much credit to Theodore de Quincey who was among the first to apply quantitative methods to fertilizer investigations. His work, continued and developed upon by Boussingault and Tiers, opened the way for a great deal of the scientific research since that time. Tiers placed all emphasis upon the analyses of the soil of plants, but it is now found that merely quantitative analysis does not sufficient, and therefore it has become common practice today to use the most biologically active mineral constituents in the soil and green plant tissues as a better guide to the nutrient needs of plants.

The culture of turnips has been intensively studied by researchers to determine the concentrations and ratios of nutrients which might result in greater yields. Facts are known to be extremely responsive to the application of nutrient elements. This study was therefore undertaken to determine the effect of different concentrations, and interrelationships of nitrogen, phosphorus, and potassium on the growth and characteristics of sugar beets and table beets and to establish the optimum source and levels of nutrient concentrations for these crops.

## REVIEW OF LITERATURE

Ulrich (28) found that the concentration of nutrients in plants was a function of the time, plant, climate, and management practices. He also stated that the minimum growth possible within the limits of supply of a single element can result only when the concentration of all elements have been brought into balance at the level of intensity determined by that element. "At any level of nutritional intensity there exists a balance of nutrients at which optimum growth for that intensity level will result..." Further, at any level of nutritional intensity, provided that all nutrient elements are in proper balance, it is possible to obtain plants that appear normal in every respect and in which all metabolic processes are probably quantitatively normal. However, maximum growth and yield result only when the proper balance of nutrient elements occurs in combination with their optimum intensity. It is possible to have plants lacking in distinctive symptoms of malnutrition, but which fail to produce maximum yields.

Lunderdahl (20) observed that leaf analysis gives the direction and extent of nutritional unbalance within the plant and provides the knowledge whereby the proper balance between fertilizer elements may be determined when fertilizer applications are made under various soil and cultural conditions.

Weidemann and Cook (33), after a greenhouse study of the deficiency symptoms of sugar beets grown in quartz sand, found the following: "Nitrogen deficient plants were very small, but had healthy appearing roots and spreading pale green leaves which developed

a slight pinkish tinting, with an increase in size. Plants deficient in phosphorus were very small with deep green, erect leaves, and red stems or crowns. The tap roots were small and covered with fine black roots..." Potassium deficient plants grew larger, but required more potassium to keep them alive. These plants became yellow and necrotic along the borders of their leaves.

Demidenko (11) concludes: "Nitrogen is required by sugar beets throughout the growth period. The time of the development of the four to seven pairs of leaves should be considered the most critical with respect to nitrogen..." The cutting off of nitrogen reduced both the yield of the roots and leaves. The excluding of nitrogen from the nutrient solution at the period of seven to ten leaf formation reduced the amount of soluble nitrogen; plant uptake of phosphorus as well as potassium was decreased, and the deficiency of one of the most important elements prevented the normal development of the organism as a whole.

By conducting other field experiments, Decoux and others (10) found that large applications of potash alone did not greatly change the expressed juice of sugar beet roots. Leaf growth, however, was found to have been influenced greatly by doses of nitrogen and potash. Potash in excess of the plant's needs was found to be stored in the leaves. Heavy applications of nitrogen in the absence of potash produced marked injurious effects.

Demidenko (12) also found that a lack of potassium during early stages of the development of sugar beets resulted in reduced yield

and increased after the crop. The first year, when the potassium uptake was found to be 1% of that of the phosphate solution during the period of the seven to ten leaf formation, translocational potassium during the second half of the spring season resulted in an increase of soluble nitrogen and the maximum uptake of potassium was found to coincide with the critical period of potassium nutrition.

Schindler (24) summarized results of the application of commercial fertilizers on sugar beets over a period of twenty years in the Arkansas Valley of Colorado and found a general need for phosphate containing fertilizers. Cinnison (5) found that manganese was probably the limiting factor in the growth of sugar beets when exceeded by other factors. Frank and others (75) concluded that at given phosphate values, the response to manganese increased with the clay content and acidity of the soil.

Atkinson, Hart, and Lentle (2) found that the amount of manganese and potassium was usually increased in the plant tissue when these materials were applied in a fertilizer. When nitrate concentrations were increased, phosphate diminished and when nitrogen decreased manganese increased.

Dorn and Post (13) state: "Fertilizers had a significant greater influence on the yield of roots than on the tops of sugar beets, but high yields of tops were generally associated with high root yields." Phosphate and manure fertilizers had some influence on the development of sugar-beet tops, particularly on soils where there was a deficit of these minerals. Treatments with carriers of long-chain organic acids highly reduced the manganese in the beet foliage.

In experimental work on table beets, Blackman, Newman, and others (3) found evidence that the yield of tops was less with low fertilizer treatments, and the size of the beets was larger on plots where complete and double treatments of fertilizers were added. Low temperature produced anthocyanin pigments, while high temperature and the abundant production of foliage caused this pigment to break down. Double applications of phosphorus produced the best normal color of the beets, while a deficiency of phosphorus resulted in the poorest color.

Fudzhayseva (18) studied the effects of fertilizer applications on various vegetables and found that table beets responded more to potash fertilizers than did any of the other vegetables studied. Smith and Schlenker (25) concluded from their experiments on the optimum soil nutrient levels for table beets that growth on plots with less than 10 p.p.m. nitrate was slow and took place at the expense of the nitrate reserve in the soil. At 25 p.p.m. there was greater response, especially where the number of plants was low, but maximum yield was not obtained until the 50 p.p.m. level was reached. The concentration of nitrogen in the expressed juice correlated with the growth rate of the beets. Less than 500 p.p.m. nitrate in the midrib correlated with the retarded growth rates. The nitrate concentrations in the midribs were greater where the best response was obtained.

## EXPERIMENTAL METHODS

### SOIL

Oshkosh loamy sand was selected as the soil in which to grow beets. Oshkosh, according to J. O. Ventch (30), includes light brown loamy sands and sandy loams, underlain by pervious sand with small admixtures of clay and gravel, and it is very low in fertility.

The nutrient levels in Oshkosh were determined by using the Sharway active test (26) and were found to be less than 1 p.p.m. nitrogen, 3 p.p.m. potassium, and 2 p.p.m. phosphorus. The pH was 5.0. All grass was scraped off, and only the first eight inches of top soil used. This was screened and air dried before it was potted.

Oshkosh was chosen because of its low fertility level. Since it is low in organic matter and clay content, interfering ions and colloids were mostly avoided and the problem of establishing an index of the nutrient requirements was greatly simplified.

### FIXATION TESTS

Since the objective of this experiment was to measure the response of the beet crops to the available nutrients, the problem necessitated the establishing of the amount of minerals required to bring the soil to various levels of actively available nutrients so that the response could be studied at these different levels.

The soil was therefore calibrated by running tests to determine

the fixing power of Osktero for nitrogen, phosphorus, and potassium when applied in the form of the mineral salts that were used in this experiment (Table 1). The fixation test for each element was run by weighing out twenty-four 250 gram samples of air dry soil to serve for twelve treatments in duplicate. The treatments included twelve levels each of nitrogen, phosphorus, and potassium. The soils were then brought to maximum water holding capacity which was kept constant at room temperature for two weeks. The Sprout test was then used to determine the active or available nutrients. The calibration curves shown in Figs. 1, 2 and 3 were drawn from the data obtained in these tests.

A look at these curves shows that the fixation of nitrate by Osktero resulted in a straight line relationship. In other words, the nitrate in the soil was directly proportional to the nitrate that was added. This is shown by the constant value of the slope of the curve throughout its entire length. Phosphorus was fixed to the greatest extent and the percentage of fixation decreased as larger quantities of phosphorus were added. Proportionally it was much less available when small increments of monocalcium phosphate were added than when larger applications were made. This is shown by the more rapid rise of the curve with increased increments of added phosphorus. The potassium fixation curve shows that there was also a slight decrease in percentage fixation as greater quantities of sulfate of potash were applied.

#### TREATMENTS

A 4 x 4 x 3 factorial design was chosen to carry out the

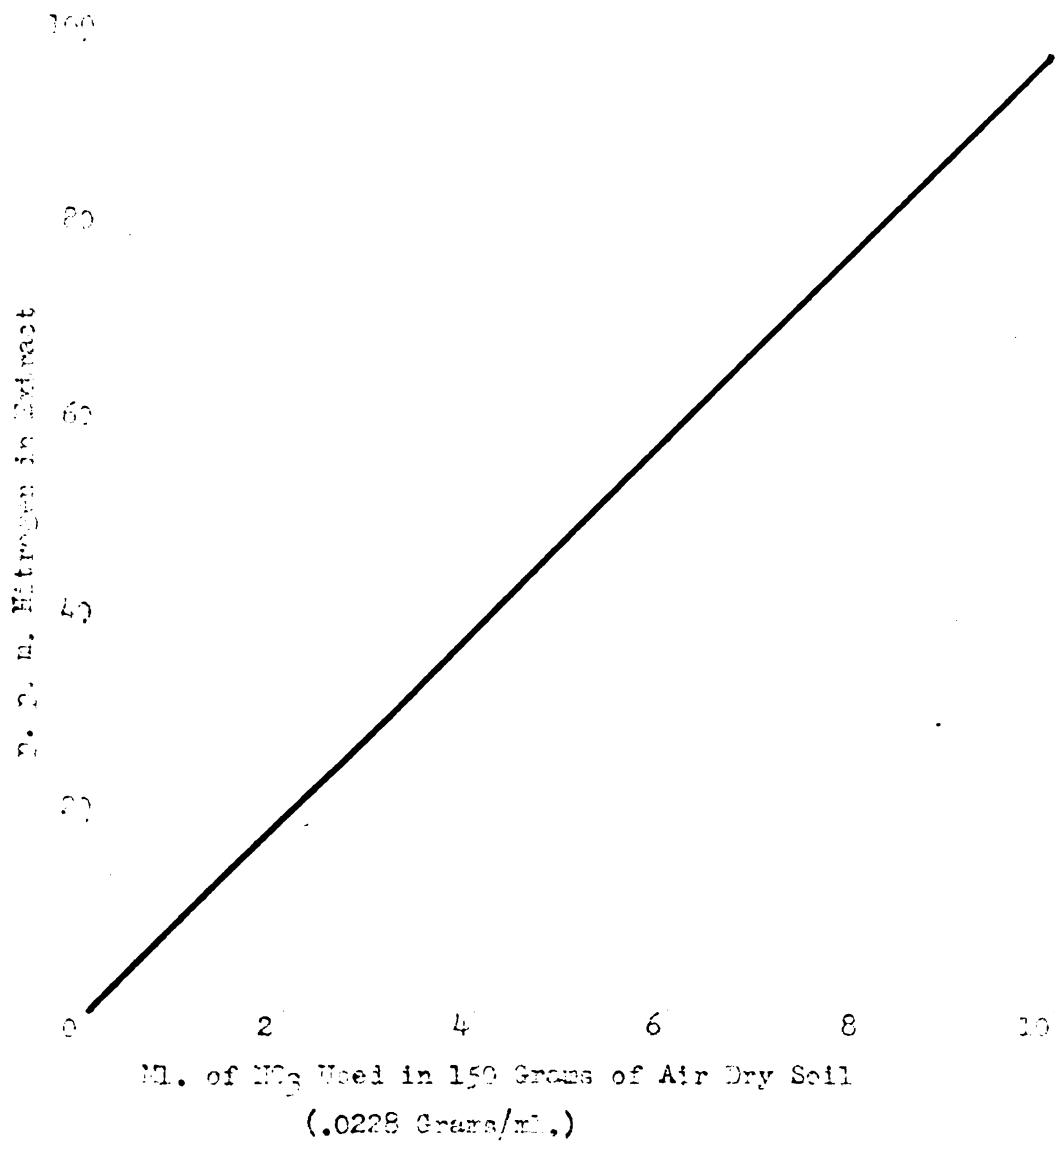

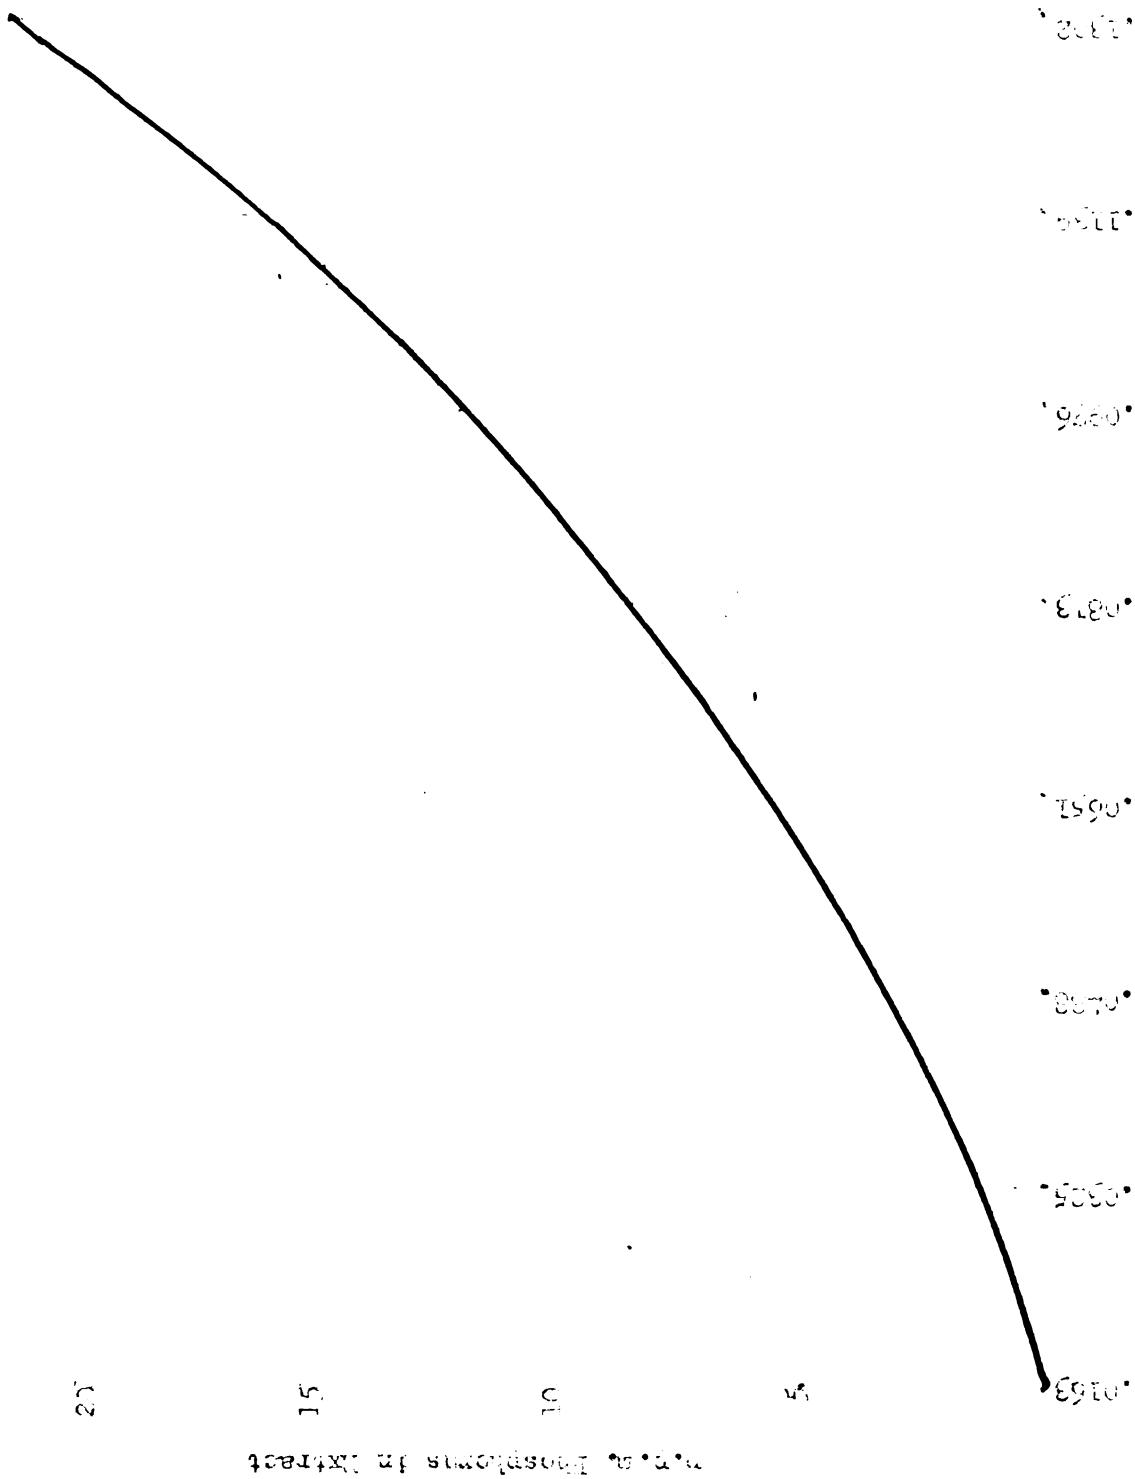

FIG. 2. — Phosphorus fixation by *Cathartes* (3).

Grams of Monocalcium Phosphate per 100 Grams of Air Dry Soil.

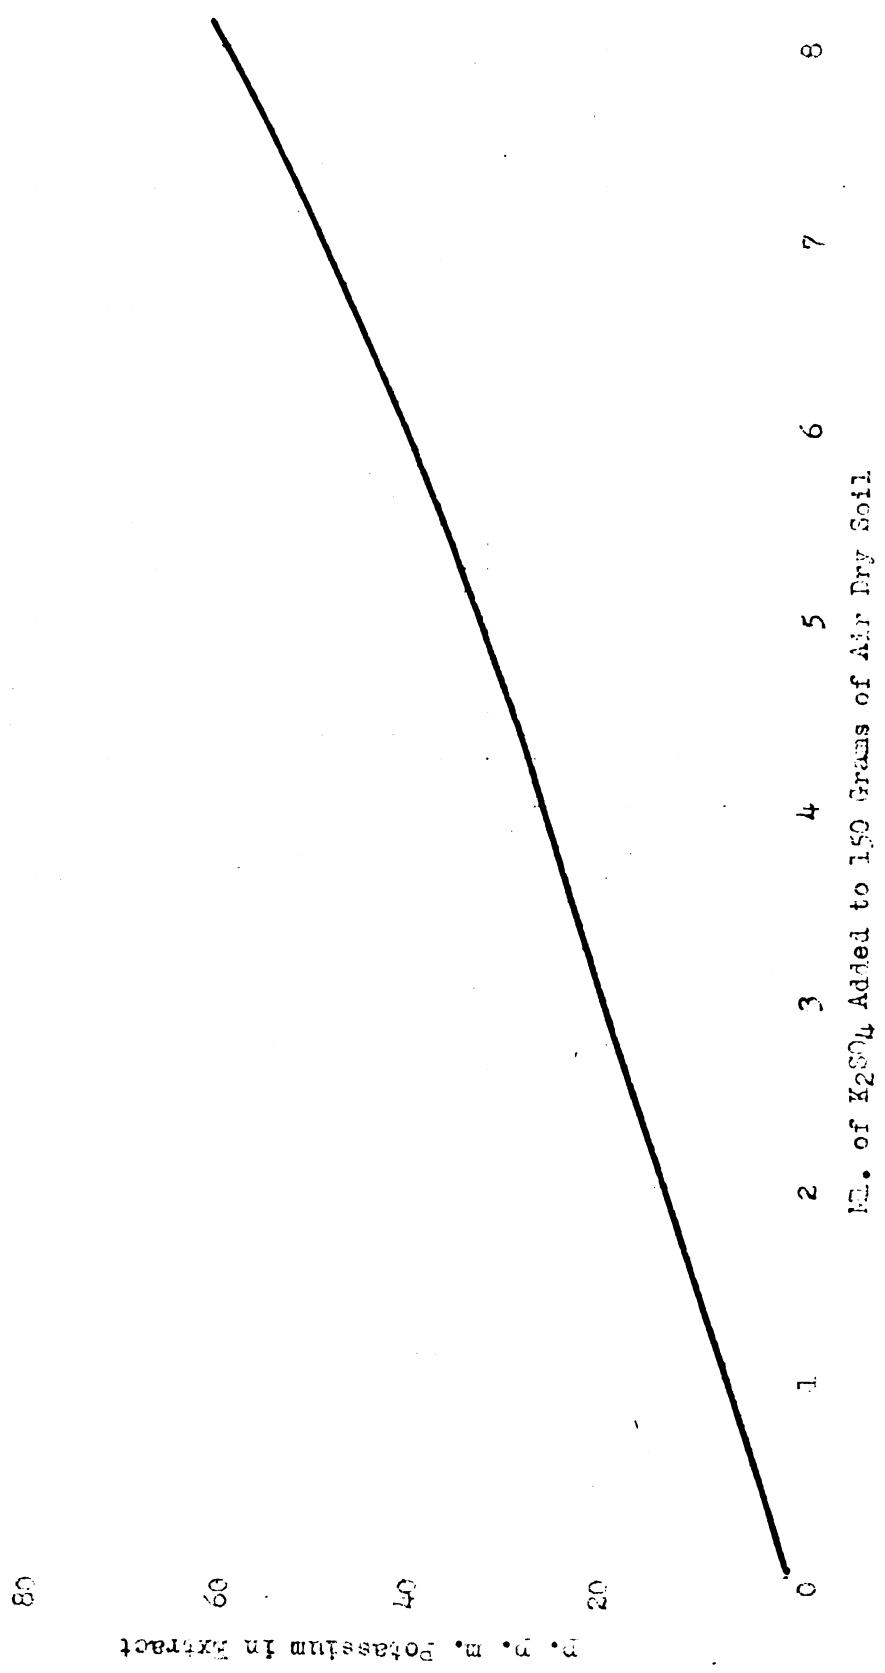

Fig. 3. — Potassium fixation by Ostrich (S2)

(0.02 Grams/ml.)

experiment. The four levels of nitrogen selected were 0, 25, 50, and 100 p.p.m.; potassium levels chosen were 0, 15, 30, and 60 p.p.m.; and the three levels of phosphorus selected were 0, 5, and 10 p.p.m. This gave a total of forty-eight treatments (Table 1) which were duplicated for both sugar beets and table beets, making a total of 192 pots. As in the fixation tests, monocalcium phosphate and sulphate of potash were used as carriers of phosphorus and potassium, respectively. There was a split application of the nitrate. One-half of the required nitrogen was furnished by ammonium nitrate with the other half being obtained from nitrate of soda. This was done to avoid the possibility of injury from too much sodium. Even though much evidence has been presented to show the beneficial effect of sodium for sugar beets and table beets (19), excessive concentrations might have seriously complicated this experiment. Complications resulting from high concentrations of sodium would be quite likely to develop in a sand such as Oshtero where the buffer capacity of the soil is low. Also sodium nitrate would tend to offset the acid reaction promoted by large applications of ammonium nitrate (22). Beets are particularly sensitive to the deficiencies of manganese, magnesium, and boron (16). Therefore, to prevent any interferences by the malfunctioning of the physiological activities within the plants or the development of deficiency symptoms due to a lack of these elements, the following steps were taken: Manganese and magnesium sulphates were applied at the rate of 100 lbs. per acre and sodium tetraborate at the rate of five pounds per acre. Beets are lime loving crops and do best in a soil with plenty of calcium (17).

Therefore, four grams of calcium carbonate was added to each pot.

The pH was raised from 5.0 to approximately 6.5.

Nine kilos of sand was placed in two- liter pots that had been previously weighed. The soil was dumped into a mixing pan and thoroughly mixed after treatment. To apply nitrogen and potassium, the salts of these elements were dissolved in distilled water and the proper volume measured to raise the nutrients to the selected levels (Table 1). Volumes were adjusted to fit standard pipettes and then the nutrient concentrations per c. c. were calculated in order to facilitate the addition of the treatments. The quantities of fertilizer materials needed to raise the soil's active nutrients to the selected levels had already been determined by fixation tests (Figs. 1, 2, 3). Manganese, magnesium, and boron carriers were equally added to all pots at this time. The low solubility of monocalcium phosphate made it necessary that it be applied in the crystalline state. Calcium carbonate was also applied in a dry form.

#### GERMINATION AND LABORATORY PROCEDURE

Because this light textured soil had a tendency to wash badly, the moisture content of the soil was raised to 18 per cent of its dry weight with distilled water before the seeds were planted. The moisture equivalent of Oshtemo was not used as a basis for optimum moisture because it was found to be too low. The 18 per cent figure was arrived at by taking a tumbler of soil and measuring the amount of water necessary to moisten the soil without having any

free water in the bottom of the tubbers.

Sugar beets were planted April 27 and the table beets on April 29. On May 6, the nutrients were checked and conductivity tests were run to determine the soluble salt content of the soil. Spurway's system (26) was used to determine the nutrient levels, and color comparisons to determine the phosphorus and potassium concentrations were made with a Unicron Colorimeter (Figs. 4, 5). Proper growing space was provided by thinning the sugar beets to three plants per pot and the smaller table beets to five plants per pot. The berches were rolled out into the open on May 21 in order to avoid the excessive heat of the greenhouse and for better temperature control (3). The nitrogen levels were also checked at this time. On June 1 nitrate applications sufficient to restore the original levels were made. On June 13, pictures were taken to show the effect of the four nitrate levels, see Figs. 12 and 22. The levels were also restored on that date. Later, on June 25, the potassium concentrations were adjusted to their original levels (Table 5).

On July 11 the beets were harvested and the pictures shown as Figs. 13, 14, 23, and 24 were taken. The tops and roots were dried separately and weighed. Then the dried tissue was ground in a hammer mill, and total phosphorus determinations (28) were run on the composite replicates of roots and tops for both sugar beets and table beets. The procedure for the phosphorus determination was as follows: One-half-gram samples were weighed on an analytical balance and placed in porcelain crucibles. After this each sample was treated with 2 ml. of 1.0 molar ammonium nitrate and 0.2 molar manganese

nitrate solution. This was digested to a volume of one milliliter of 5000 ppm for four hours and the solution diluted to 100 ml. of 2 percent acetic acid. From this 5 to 50 ml. were taken up to 50 ml. and finally 10 ml. of the buffer was used to determine phosphorus colorimetrically, using F and S reducing agent (16). The readings were made with a Unicron colorimeter.

#### MANAGEMENT OF EXPERIMENTAL PLANTS

The soil was tested by using the Simpex soil testing system (26). The levels were checked about every two weeks. A soil sampling tube was used to take the sample which made it possible to remove a column of soil that represented a true cross section of the growing medium extending from the top to the bottom of the container. The column of soil was dried and thoroughly mixed.

The nutrients in the soil were extracted by using 0.02% acetic acid with a soil-extract ratio of 1:4. Nitrate determinations in the extract were made with diphenylamine in concentrated sulphuric acid according to the specifications of the Minnesota Agriculture Experiment Station Technical Bulletin, 132, 1919 (26). Phosphorus and potassium were also determined by the Simpex active test. Volumes of soil and extracting solution were of sufficient size to make possible the use of a colorimeter. Standard curves for determining the quantities of nutrients in the extract were drawn by developing known concentrations of these elements and plotting their per cent transpiration against concentration (Tables 4, 5). From the soil test results it was possible, by use of the curves shown in

Figures 1, 2, and 3 are descriptive elements of movement analysis necessary to restore the skills to their original movement level.

## PLANTING AND HARVESTING

### SUGAR BEETS

Nitrogen. Of the three elements which were applied in the various concentrations and combinations shown in Table I, nitrogen caused the most pronounced effects on growth. This is indicated by the data represented in Table 2. It is graphically shown by Figs. 6 and 7 that the yield of sugar beet foliage reached a maximum at the 50 p.p.m. level, while the yield of roots was greatest at the 25 p.p.m. level. This indicates that up to the time of harvesting, nitrogen stimulated sugar beet roots to maximum production at a lower level of intensity than it did for sugar beet tops. However, the reduction in the yield of roots between the 25 and 50 p.p.m. levels, a little over 2 grams per plant, was probably too small to be significant. It therefore seems that the optimum growth of sugar beets, as a whole, came at the 50 p.p.m. level.

Statistical analyses (Tables 9 and 10) show that the nitrogen fertilizers produced highly significant increases in the yield of sugar beets. The F values show that the tops responded more than did the roots. The figures in Table 10 indicate that 100 p.p.m. of nitrogen increased sugar beet yield 17.4% and 100 p.p.m. of phosphorus increased sugar beet yield 10.7%. The figures in Table 10 also compare the effect of the two major fertilizers (nitrogen and phosphorus) with the phosphate and potassium salts. This is shown by an analysis of variance given in Tables 9 and 10. There was not a significant difference between

nitrogen and phosphorus and potassium ratios as well as moisture.

The fact that nitrate varieties responded better to the first addition of nitrogen than did the different phosphate and sulphate varieties or near their original levels. Table 2 shows below the tests and averaging of nitrogen over the period in which the experiment was carried out. Some difficulty was experienced in making determinations for nitrogen, especially at the higher levels. Numerous dilutions had to be made to bring the readings within the range of the comparison charts (26). For that reason the accuracy of some of the determinations is probably questionable. As can be seen in Table 2 the highest levels of nitrogen concentrations had not diminished sufficiently at the time of the first addition of nutrients to register a loss in nitrogen.

Hunger symptoms due to shortages of nitrogen were the first deficiencies noticed on both crops. These grew progressively more evident with the growth and development of the plants. Sugar beets that did not obtain sufficient nitrogen were greatly reduced in size (Fig. 11), and the foliage generally possessed a pale green color. Roots that were grown in nitrate deficient soil were also restricted in size (Figs. 13 and 14). Where nitrogen was low, the plants' lower leaves gradually turned from light green to deep shades of yellow, then finally died.

Phosphorus. Phosphorus produced highly significant increases in the yields of the top and roots of sugar beets (Table 9 and 10). Previous investigations (22) and long time varieties in the state of

It is an interesting fact that a certain amount of phosphorus must be present in the soil for the best favorable conditions of this crop. The optimum concentration of phosphorus is practically represented by Figs. 8 and 9. The 5-p.p.m. phosphorus level proved to be the most desirable. As shown by Fig. 9 there was a very slight further increase in yield at the 10-p.p.m. level. However, this small increase was not significant.

The data reported in Table 8 revealed a negative correlation between the yield of sugar beets and the concentration of total phosphorus in the dry tissue. Correlation showed the correlation coefficient to be -0.6, highly significant. The data (Table 8) show also that there is a direct relationship between the decrease in total phosphorus per gram of plant tissue and the quantity of nitrogen and potassium added as fertilizer. Thus it seems that the absorption of phosphorus very definitely tended to increase where there was a deficiency of nitrogen and potassium (9).

This, coupled with luxury consumption induced by excessive applications of phosphorus, probably accounts for the super abundance of this element in the beet tissue. According to Collines (6) sugar beets grown under field conditions contain approximately 1500 m.p.m. of phosphoric acid which is considerably below the figures given here. However, it should be pointed out that the age and maturity of the plants may also have contributed to the high proportion of phosphorus absorbed. It is a known fact that some plants can absorb enough phosphorus within the first few weeks of their growing season to insure a supply that is sufficient to take care of their needs during the remaining period of growth. It may be assumed, then, that if given sufficient

time for growth and development. The concentration of the concentration of phosphorus in the leaf tissue to the weight of the foliage would be greatly diminished.

There was significantly higher uptake of phosphorus by the plant foliage than by the roots. This may be expected since phosphorus takes up a part of the nuclear proteins and also probably functions in the formative processes that go on within the plants (21).

Up to the time of harvesting, except for a difference in the size of the plants, there were no visible differences resulting from the phosphorus treatments.

Tops were consistently heavier than the roots, the root-top ratio being 0.72 as an average for the 96 pots in the experiment. Perhaps the root-top ratio would have changed if the beets had been allowed to mature. In a report by Schreiner and Brown (23), the tops of sugar beets represented 22 per cent of the entire crop. It is logical to suppose that if the period of growth had been extended in this experiment, the root weight of sugar beets might have surpassed the weight of the foliage. The roots, being primarily storage organs, should develop at a more rapid rate after an adequate leaf surface had been formed.

This also leads to the belief that with an advance in the stage of maturation of the sugar-beet plants, more response to the phosphate treatments might be expected. Brown and Irving (4) have shown that beets build up a high concentration of phosphorus during the first half of the growing season in order to furnish the roots with phosphorus during later stages of development. It then appears likely that the developing leaves might have priority on the phosphorus supply during

The early stages of growth. If there is a shortage of this element at this stage, the deficiency symptoms might then readily appear in the leaf area at the time when the root requirement begins to demand translocation from the tops.

Generally, characteristic inner signs for phosphorus show up early in the life of the plant. It is believed that if the untreated soil contained enough phosphorus to prevent these symptoms from appearing,

Potassium. The analysis of variance (Tables 9 and 10) show that there was a highly significant response to potassium. Maximum production came in each case, for roots and tops, at the 30 p.p.m. level of potassium. Figures 10 and 11 show that the need for 30 p.p.m. of potassium, as compared to 15 p.p.m. was greater in the case of roots than for tops. The interaction between potassium and the other elements (nitrogen and phosphorus) was not significant (Tables 9 and 10).

Where no potassium was added the plants showed the characteristic visual symptoms of potassium deficiency. The older leaves turned brown around the margins and the interior of the leaf became crinkled and curled. The most severely deficient leaves were almost entirely necrotic at the time of harvest. Many of the necrotic leaves became broken and frayed as they were moved about.

The more pronounced cases of potassium deficiency occurred at higher levels of phosphorus and nitrogen (Fig. 15). No doubt, the intensified imbalance resulting from greater intake of nitrogen and

zhesphorus, where five elements were high was responsible for these more strongly defined potassium deficiency symptoms. It has been shown (2, 22) that deficiency symptoms due to the insufficient uptake of one element are more marked when a soil is well supplied with the other fertiliser elements than when there is a deficiency of all elements with a balanced ratio at the lower level.

phosphorus level was ten and the nitrate level was  
twenty-five p.p.m.

## TABLE BEETS

Nitrogen. As was found for sugar beets, nitrogen also caused a greater growth response in table beets than did either phosphorus or potassium. As shown by the data presented in Table 37, the profile of the assimilation of nitrogen for table beets generally paralleled that of nitrogen for sugar beets.

Table beets, roots and tops, reached their maximum production at the 50 p.p.m. nitrate level. The production of table beet tops averaged approximately four times as much dry tissue at the 75 p.p.m. level as was obtained at the zero level of nitrate concentration (Fig. 16). An increase of an additional 25 p.p.m., to 50 p.p.m., at which maximum growth was obtained resulted in only a very small further increase in yield. At the 100 p.p.m. level the high concentration of nitrate salts was injurious. This was evident by a slight depression in top growth and a very serious depression in root growth, as shown by Fig. 17. As with the tops, the marked increase in yield of roots as a result of the first increment of nitrogen was followed by a very slight further increase, as the level of nitrate was raised to 50 p.p.m.

The high significance in the response of table beets to nitrogen fertilizers is shown in the analysis of variance tables (Tables 12 and 13). These tables further show that the interactions of nitrogen, phosphorus, and potassium were not significant. It is clearly apparent from the data that nitrogen caused a notably higher stimulation to the top growth of the beets than to the growth of the roots. In addition,

the response was highly significant.

Visually, table beets grown in soil low in nitrogen varied from reddish to a purplish bronze color. This was also characteristic of phosphorus deficient plants. Since nitrogen is essential in the formation of the plant's protoplasm, it is intimately associated with phosphorus in the growth processes that go on within the plant. Both are indispensable in the synthesis of nuclear proteins which are found in the cell's interior and function in nuclear division and cell enlargement (21). Therefore, without nitrogen there could be little assimilation of carbohydrate. The carbohydrate, instead, was diverted to the formation of anthocyanin pigments which appeared in the form of the deep bronze to reddish color of the beet's foliage. In this respect table beets differed from sugar beets which did not show evidence of the production of anthocyanin. Other visible nitrogen deficiency symptoms were not different from those of sugar beets, namely, stunting and death and shedding of the lower leaves.

Phosphorus. There was general response to phosphate fertilizer by table beets, though the degree of response was greater for tops than for the roots. The statistical analysis reported in Tables 12 and 13 show the effect of phosphorus on the tops to be highly significant while for the roots the response was not significant. The greatest increase in the yield of dry tissue came at the 5 p.p.m. level for both tops and roots (Figs. 18 and 19). The response shown here is similar to the results obtained for sugar beets, in that both crops make their best growth at 5 p.p.m. available phosphorus. This shows again the similarity between the two plants in their requirement for nutrients.

The first column presents the data obtained by applying the method to Table 1. It is seen that the total nitrogen content of the fertilizer was consistently higher than that of the manure alone due to the addition of added nitrogen and potassium.<sup>(2)</sup> There was a slight tendency for the yield to increase more rapidly than the nitrogen content, but this was only a result of this element not being applied except at intermediate rates. On continuing nitrogen application, it was found that the maximum yield obtained was 2 per cent. and 13.7 per cent., respectively, when nitrogen applications were 0.15 and 0.25 per cent. The addition of phosphorus and potassium to the manure increased the yield about 10 per cent. and 15 per cent. when 0.15 per cent. of each element was applied. An even greater reduction in phosphorus was noted for the manure alone. Addition of potassium caused the disappearance of the manure trace of phosphorus. When the phosphate material was applied to the soil, nitrate fertilizer, in the highest concentrations, reduced the phosphate content of the foliage by 205 per cent. A combination of nitrogen and potassium at their highest levels caused the ratio of phosphorus to be only 22 per cent. of what it was when neither of these elements was added.

The highly significant correlation coefficient of 0.95 was calculated by the method of least squares for a plot of total nitrogen to the leaf area and quantity of chlorophylls observed for all treatments. Thus, like sugar-beets, an inverse relationship between dry weight of leaves and chlorophyll content is evident, showing that the effect of added potassium is indirect, since the effect of potassium will be accompanied by growth.

Typical results (Fig. 21) taken from the tree leaves of *Phaseolus vulgaris* at different treatments were utilized for the analysis of variance.

of the root crop, and to some extent to the tops. It may be pointed out that even though the tops were taken up as a result of greater availability of phosphorus, which is particularly true for the tops, the plants which did not receive fertilizers were normally proportioned and the roots were like those grown under optimum concentration and balance of nutrients (22).

The off-color of table-beet tops, induced as a result of phosphorus deficiency was very much the same as that described for carrots grown in soil low in nitrogen. The off-colors of copper and boron appeared more intense where nitrate and phosphate deficiencies were accompanied by high potassium. According to Kefler and Wright (17), these two elements (phosphorus and nitrogen) are so interrelated that there is no assimilation of nitrogen without phosphorus taking part in the reaction. It appears that these anthocyanin pigments are excessively produced in table beets and certain other plants whenever the photosynthetic processes in the plant are adversely affected by a deficiency of phosphorus.

**Potassium.** The general effect of potassium was to increase yields of both tops and roots. As was true for sugar beets, the roots of table beets were especially responsive to potassium treatments. The data given in Table 11 and illustrated in Figures 20 and 21 furnish evidence that the addition of potassium to the soil notably contributed to the quantitative development of the root crop.

It is of interest to note that the pattern of response resulting from potassium applications was similar for roots and tops. However,

The most pronounced symptom observed was a reduction of the percentage of roots at the 30 percent level of concentration. It was diminished by 8 percent at the 60 percent level. The plants also registered a reduction at the 30 percent level, but leveled off and maintained this same rate of reduction at the 60 percent level. Further examination of these data, as shown by the analysis of variance (Tables 12 and 13) indicates that root tops yields were significantly increased where potassium was applied and that the increase was highly significant in the case of the roots. At the harvest date the ratio of roots to tops had reached a value that averaged 1.1 for the 36 pots in the experiment. This higher proportion of roots to tops distinctly contrasts with the proportion of sugar beet roots to tops. In the latter case the root-top ratio was 0.72, a greater yield of tops than roots. The difference here evidently resulted because of differences in the length of time needed for the plants to mature. Table beets are usually mature enough to harvest in 50 to 60 days after planting. On the other hand, sugar beets require more than twice this length of time to give the best yield of roots.

Visible injury signs appeared in the form of restricted growth of the entire plant. Diminished growth was accompanied by drooping foliage that was especially noticeable in the lower leaf area where necrosis occurred along the leaf margins. Many of the lower leaves died which gave the plants the same frayed appearance that was shown by sugar beets.

The nitrogen deficient plants were greatly reduced in size, yellowish and slightly bronzed in color. Greatest growth occurred at the fifty p.p.m. level.

Fig. 23. -- The Effect of nitrate levels on the growth of table beets. (1) zero, (2) twenty-five, (3) fifty, and (4) one hundred p.p.m. Phosphorus and potassium were not added. Note the highly significant response at the twenty-five p.p.m. level as compared to level No. 1.

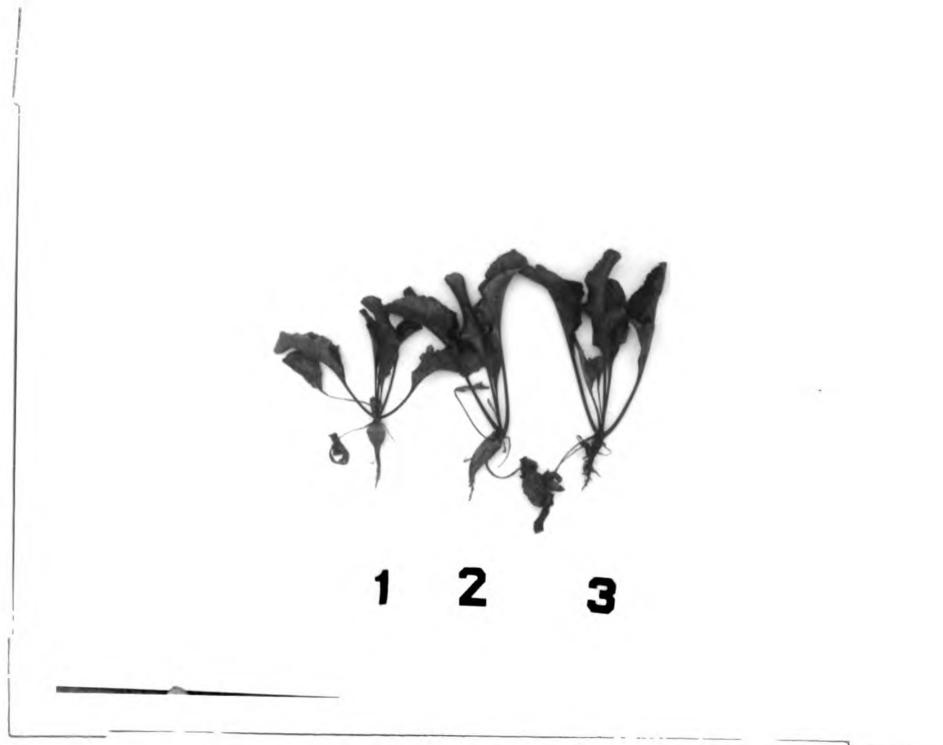

Fig. 24. -- Table beets showing successive levels of zero, five, and ten p.p.m. phosphorus at zero levels of nitrogen and potassium. Limited response to phosphorus is shown. Five p.p.m. phosphorus gave the greatest yield.

## SUMMARY AND CONCLUSION

Sugar beets and table beets were grown in pots of Oshkosh loamy sand. Levels of nitrogen, potassium, and phosphorus were arranged as a  $4 \times 4 \times 3$  factorial experiment. A study was made of the effect of the variable nutrient levels on the production and visible characteristics of these two crops and on their content of phosphorus.

Nutrient levels were maintained by testing for the active portion of fertilizer elements in the soil by using Sperry's Nitrex system. Color concussions were made with a colorimeter for greater accuracy in determining phosphorus and potassium. Determinations for total phosphorus absorbed by the plants were also run and its uptake correlated with plant yield and the rates of application of nitrogen and potassium.

There was a great deal of similarity in the response of table beets and sugar beets to the fertilizer treatments. The greatest stimulation of crop production by a single element was produced by nitrogen. This was probably due, in part, to the tendency for nitrogen to stimulate vegetative growth and to the very low level of nitrogen in the untreated soil. Maximum yield of tops resulted at the 50 p.p.m. for both crops, but for the roots the results from the two crops varied somewhat. For table beet roots, maximum yield occurred where the nitrate level was 50 p.p.m. but that level was too high for sugar beets.

A deficiency of nitrogen greatly diminished the yield of both

beet crops and resulted in excessive amounts of anthocyanin pigments in table beets which caused the foliage to have a deep reddish to brown color. The tops of sugar beets appeared yellowish in varying degrees of intensity depending on the extent of nitrogen starvation. In the more extreme cases of nitrate deficiency, chlorosis was followed by dying and shedding of the lower leaves.

Phosphorus significantly increased the yield of table beets and sugar beets. The optimum level of this nutrient was found to be 5 p.p.m. Phosphorus in the tissue of beets when correlated with yield revealed that yield and phosphorus uptake were inversely related. The same relationship was found between total phosphorus in the rhizome and the quantity of nitrogen and potassium applied. Phosphorus absorption was greatly increased where there was a shortage of the other fertilizer nutrients and diminished as the supply of nitrogen and potassium increased.

Plant size constituted the only visible symptom of phosphorus deficiency in sugar beets. Besides diminished yield, table beets showed a greater intensity of anthocyanin production where low phosphorus was coupled with a deficiency of nitrogen. These conditions appeared more conspicuous where the above conditions were aggravated by high potassium applications.

Thirty p.p.m. potassium was found to be the critical level in the nutrition of each beet crop. Tops and roots responded readily to potassium. The increase in root yield as a result of added potassium proved to be more significant than did the increase in the foliage.

Roots grown in potassium-deficient soil developed necrotic and frayed margins on the lower leaves. Slower growth of the leaf-rings resulted in crinkled leaves, and where there was an extreme shortage of potassium the oldest leaves died.

In pointing out the differences and similarities between table beets and sugar beets, it was found that the two plants closely paralleled each other in response to the various fertilizer treatments. However, variations in the length of growing season for the crops probably account for the relatively wide differences in the rates at which the roots developed in relation to the tops. Since the table beets needed a much shorter period to mature, they had a larger root-top ratio than did the sugar beets when the plants were harvested. Sugar beet root yields were 28 per cent lower than were the top yields. On the other hand, the average weight per pot of table beet roots was 10 per cent greater than that of the corresponding tops.

Except for the visible discolorations due to the accumulation of anthocyanin pigments in table beets where nitrogen and phosphorus was low, sugar beets and table beets reacted to the fertilizer treatments much in the same way, from the standpoint of symptoms. At lower levels of nutrient concentrations where fertilizer elements were not sufficient for maximum production but were more nearly balanced, the plants, though small were more nearly normal in appearance than those at higher levels where the relationship between the nutrients was greatly unbalanced.
